By using of a model for the propagation of the emitted X-rays through the infalling material and the reemission of the energy deposited by photoabsorption in the optical (and UV) spectral range (Kim & Beuermann, 1995) we calculated H $\gamma$  line spectrum of intermediate polars. Photoabsorption of X-rays by the infalling material is the dominant process in forming the observed energy-dependent rotational modulation of the X-ray flux. X-ray and optical modulations are sensitive to model parameters in different ways. In principle these dependences allow to obtain improved insight into the geometry of intermediate polars. Some results of our calculation will be presented in this paper in comparison with the H $\beta$  spectrum calculated by Kim & Beuermann (1996).
