Abstract

Inositol hexaphosphate (IP₆) is a major constituent of most cereals, legumes, nuts, oil seeds and soybean. Previous studies reported the anticancer effect of IP₆ and suggested that co-treatment of IP₆ with inositol may enhance anticancer effect of IP₆. Although the anticancer effect of IP₆ has been intensively studied, the combinational effect of IP₆ and inositol and involved mechanisms are not well understood so far. In the present study, we investigated the effect of IP₆ and myo-inositol (MI) on cell cycle regulation and apoptosis using PC3 prostate cancer cell lines. When cells were co-treated with IP₆ and MI, the extent of cell growth inhibition was significantly increased than that by IP₆ alone. To identify the effect of IP₆ and MI on apoptosis, the activity of caspase-3 was measured. The caspase-3 activity was significantly increased when cells were treated with either IP₆ alone or both IP₆ and MI, with no significant enhancement by co-treatment. To investigate the effect of IP₆ and MI on cell cycle arrest, we measured p21 mRNA expression in PC3 cells and observed significant increase in p21 mRNA by IP₆. But synergistic regulation by co-treatment with IP₆ and MI was not observed. In addition, there was no significant effect by co-treatment compared to IP₆ treatment on the regulation of cell cycle progression although IP₆ significantly changed cell cycle distribution in the presence of MI or not. Therefore, these findings suggest that IP₆ has anticancer function by induction of apoptosis and regulation of cell cycle. However, synergistic effect by MI on cell cycle regulation and apoptosis was not observed in PC3 prostate cancer cells.

Key Words: Inositol hexaphosphate, myo-inositol, apoptosis, prostate cancer, cell cycle progression

Introduction

Inositol hexaphosphate (IP₆), which is also known as phytic acid, is a major constituent of most cereals, legumes, nuts and soybean. In plants, phytic acid exists as salt with monovalent and divalent cations (Shamsuddin et al., 1997). IP₆ and lower phosphorylated inositol (IP₁₋₄) are also found in almost all mammalian cells in substantial amounts up to 1 mM (Sasakiwa et al., 1995; Shamsuddin, 1999). The second messenger role of inositol 1,4,5-trisphosphate (IP₃) in bringing about a host of cellular functions including mitosis via mobilizing intracellular Ca²⁺ is well recognized. Inositol 1,3,4,5-tetraphosphate (IP₄) and inositol 1,3,4,5,6-pentaphosphate (IP₅) have been shown to induce Ca²⁺ sequestration (Shamsuddin et al., 1997). Recently, many studies have shown several health benefits of IP₆ and anticancer efficacy of IP₆ has been observed both in vivo and in vitro studies (Vucenik & Shamsuddin, 2003). IP₆ inhibited tumor growth by induction of apoptotic cell death, cell cycle arrest and differentiation of several human cancer cell lines including colon (Sakamoto et al., 1993), liver (Vucenik et al., 1998a), prostate (Singh et al., 2003; Zi et al., 2000) and breast (Shamsuddin et al., 1996; Vucenik et al., 2005). Also, the ability of IP₆ to reduce the incidence and multiplicity of mammary tumors has been demonstrated in a variety of animal models including chemical-induced (Estensen & Wattenberg, 1993; Vucenik et al., 1995) and transplanted tumor model (Singh et al., 2004; Vucenik et al., 1998b).

Inositol phosphates are synthesized from the parent molecule inositol, and it is estimated that adults consume approximately 1 g of inositol per day (Shamsuddin, 1997). Myo-inositol (MI) is a parent compound of IP₆ and has been found in plant (Reddy et al., 1982). The addition of inositol, a precursor of inositol phosphates, to IP₆ have been shown to enhance the anticancer function of IP₆ in vivo (Shamsuddin et al., 1989; Vucenik et al., 1995). The synergistic effect may be by which IP₆ plus inositol exerts their action via lower-phosphate inositol phosphates, which serve as intracellular second messengers. Measurement of intracellular inositol phosphates after IP₆ treatment showed inconsistent change according to lower-phosphate inositol phosphates. When rats were fed AIN-76A + 1% IP₆ diet for 12 weeks, there were no significant changes in the IP₃ contents depending on IP₆ ingestion in food, while the levels of IP₃ in both brain and plasma were very sensitive to its presence in the diet (Grases et al., 2002). However, in human malignant cell lines following IP₆ treatment, the increases in intracellular levels of IP₃ or other lower phosphorylated inositolos have suggested

the important role of these metabolites as mediators of anti-cancer action of IP₆ (Ferry et al., 2002; Grases et al., 2002). In fact, cell proliferation was inhibited by inositol 1,3,4,5,6-pentaphosphate and inositol 1,4,5,6-tetraphosphate at micromolar concentrations in various cancer cells (Ferry et al., 2002; Razzini et al., 2000).

Although several studies using animal models showed the synergistic effect of IP₆ and inositol, the synergistic effect and involved mechanism are far for being understood in cancer cell lines. Therefore, in the present study, we treated PC3 cell lines with IP₆ and MI to investigate the synergistic effect along with the involved molecular mechanism.

Materials and Methods

Cell culture and treatment

The androgen-independent human prostate cancer cell line PC3 was obtained from the KCLB (Seoul, Korea). Cells were cultured in RPMI 1640 medium supplemented with 10% fetal bovine serum (Cambrex, USA), 100 units/ml penicillin, and 100 μg/ml streptomycin at 37°C in a humidified 5% CO₂ incubator (Sanyo, Japan). Cells were cultured for 24 h after plating and treated with IP₆ (0.5, 1 mM) and/or MI (5, 10 mM) dissolved in complete culture medium for 48 h. IP₆ and MI were purchased from Sigma-Aldrich (USA).

Determination of cell growth

After treatment, cells were washed with PBS and collected by a brief trypsinization, stained with 0.4% trypan blue (Invitrogen, USA), and unstained cells were counted in duplicate with a hemocytometer. The effect of each treatment on growth inhibition was assessed as the percentage of inhibition in cell growth where control cells were taken as 100% viable.

Cell cycle phase distribution by flow cytometry

The effect of IP₆ on cell cycle phase distribution was assessed using flow cytometry. Briefly, after treatment of cells, floating cells were collected and the attached cells were trypsinized and washed twice with cold PBS. Thereafter, floating cells were combined with washed attached cells and total cells were centrifuged at 100 g for 5 min, pellet was resuspended in PBS containing albumin. Resuspended cells were mixed in 70% EtOH and stored at -20°C until analysis. For analysis, cells were centrifuged and resuspended in PBS with RNAse at 37°C for 30 min. The cells were then chilled over ice for 10 min and stained with propidium iodide (50 μg/ml final concentration) for 1 h for analysis by flow cytometry. Flow cytometry was performed with a FACSscan (Becton Dickinson, Germany).

Measurement of mRNA levels by semiquantitative RT-PCR

Total RNA was isolated from the cells using Trizol (Invitrogen, USA) and RNA concentration was measured spectrophotometrically at 260 nm. The quality of RNA was also determined by running MOPS-RNA gel and the integrity of two bands was assured. Total cellular RNA was isolated using Trizol Reagent (Invitrogen, USA) and cDNA was synthesized using 2 μg of total RNA with the Superscript™ First-strand synthesis system (Invitrogen, USA). For amplification of cDNA, primers for p21 (upstream primer, GACAGCAGAGGAAGACCAT; downstream primer, TGGAGTGGTAGAAAATCTGTTCAT; 55°C) were used. Expression of β-actin was examined as an internal control (upstream primer, GTTGTGAGACCTTCAACACCCC; downstream primer, GTGGGCCATCTCTCGTGAGTCG; 60°C). For each combination of primers, the kinetics of PCR amplification was studied, the number of cycles corresponding to plateau was determined, and PCR was performed within the exponential range. Amplified products were separated on an agarose gel and visualized with ethidium bromide staining. The results were quantitated using Fluor-5™ Multimager (Bio-Rad, USA).

Determination of caspase-3 activities

The activity of caspase-3 was measured by Caspase-3 colorimetric assay kit (MBL, USA). Briefly, after treatment, cells were collected and lysed. One hundred micrograms of cell lysates were loaded into 96-well microplates, and mixed with reaction buffer and substrate for 2 h in an incubator at 37°C. Absorbance was measured using a multiwell reader (Bio-Rad, USA) at 405 nm every 30 min to confirm the linearity of absorbance. Protein content was determined using the Bio-Rad protein assay reagent (Bio-Rad, USA). Caspase-3 activity was first expressed as change in absorbance units per microgram protein and per hour and then converted to the relative value compared to control.

Statistical methods

The data were analyzed using SAS software. For all experiments, one-way ANOVA followed by Duncan’s multiple range test was employed to assess the statistical significance. Data were expressed as mean±SEM and statistical significant difference was considered to be present at p<0.05.

Results

PC3 cells were cultured for 24 h after plating and various concentrations of IP₆ and MI were added to the well, followed by further incubation for 48 h. Viable cell numbers were counted manually by hemocytometer after trypan blue staining. As shown in Fig. 1, IP₆ treatment inhibited the growth of human prostate carcinoma PC3 cells in a dose-dependent manner. Treatment of
cells with 10 mM MI significantly affected on cell number, but no significant effect on cell growth was observed by 5 mM MI. When cells were co-treated with IP8 and MI, cell growth was significantly decreased compared to those in cells treated with either IP8 or MI. However, additional inhibitory effect by different concentrations of MI treatment was not observed.

To determine the involved mechanism regarding decreased number of cells, we investigated apoptotic effect by IP8 and/or MI by measurement of caspase-3 activity. As shown in Fig. 2, 1 mM IP8 only and 1 mM IP8 plus 5 mM MI treatments significantly increased the activity of caspase-3, suggesting the possible involvement of caspase activation as one of the possible mechanisms of apoptosis induction. However, we could not observe apoptotic effect by MI alone. In addition, synergistic effect by IP8 and MI co-treatment on caspase-3 activity was not observed.

We measured p21 mRNA expression to investigate the involvement of cell cycle arrest in the inhibition of cell growth by IP8 and MI co-treatment. Eukaryotic cell cycle progression is regulated by sequential activation of various CDKs, which activities are dependent on their association with corresponding cyclins and cyclin-dependent kinase inhibitors (CDKI) (Morgan, 1995). As shown in Fig. 3, there was an upregulation of p21 mRNA level after IP8 which is consistent with the previous study using LNCaP cells (Agarwal et al., 2004). However, there was no significant difference in p21 mRNA level between IP8 treatment only and IP8 and MI co-treatment.

Because cell cycle progression is an essential event for cellular growth, we also examined whether the cell growth inhibitor effect by IP8 and/or MI is mediated through an alteration in a specific phase of the cell cycle progression. For this experiment, flow cytometric analysis of cells (both attached and floating cells) was conducted after staining cells with propidium iodide. Table 1 summarized the effect of IP8 and/or MI treatment on the cell cycle distribution of PC3 cells. Treatment of cells with 1 mM IP8 significantly changed cell cycle phase distribution compared
to that of control group by increasing cells in sub G0/G1 and by decreasing cells in G0/G1 and S phases. Although we also observed significant changes in cell cycle distribution by co-treatment with 1 mM IP6 and 5 mM inositol, there was no significant difference in cell cycle phase distribution between IP6 treatment only and IP6 and MI co-treatment.

Discussion

Although the anticancer effect of IP6 has been intensively studied, the combinational effect of IP6 and inositol and the involved mechanisms are not well understood so far. Therefore, we investigated the effect of co-treatment of IP6 and MI, which are easily consumed by the same diet such as soy, on apoptotic cell death and cell cycle regulation of prostate cancer cell PC3.

In the present study, we could not observe the significant anticancer effect of inositol on prostate cancer cell line. Although its effect was shown in some in vivo studies, its efficacy was different depending on the type of cancer (Estensen & Wattenberg, 1993; Vucenic et al., 1995). Also, there has been no previous study investigating the effect of inositol on prostate cancer cell lines. In addition, we could not observe the synergistic effect of IP6 and inositol on apoptosis of PC3 cells. Several studies proposed the underlying mechanism of synergistic inhibition of cell proliferation as the increased synthesis of low number of IPs by stimulating dephosphorylation of IP6. When HeLa cells were treated with [3H]IP6, the inhibition of cell growth was observed with increased synthesis of [3H]IP and [3H]IP1 (Ferry et al., 2002). In addition, when small cell lung cancer (SCLC) cells were treated with either IP6 or IP5, the cell growth was significantly decreased compared to that of cells treated with either IP6 or IP5 (Razzini et al., 2000). Therefore, further studies will be needed in the aspect of the synthesis of low number of IPs from co-treatment of IP6 and inositol.

Our data showed that caspase-3 activity was significantly increased when cells were treated with IP6, which is consistent with previous studies using HeLa cells (Ferry et al., 2002) and PC3 cells (Diallo et al., 2006). These consistent increases in caspase-3 activity by IP6 suggest that caspase activation might be the main mechanism of IP6-induced apoptosis in PC3 cells. The apoptotic effect by IP6 and/or MI is also consistent with FACs data, which also showed the significant increase in subG0 phase when cells were treated with either IP6 alone or IP6 and MI together.

Cell cycle arrest in either G1 phase or G2/M phase has been demonstrated as one of anticancer mechanism. Accordingly, we assessed the level of p21 mRNA and showed the significant change by combined treatments of IP6 and/or MI. As PC3 is a p53-negative cell line (Isaacs et al., 1991) unlike LNCaP cells, these modulations of proapoptotic proteins and induction of apoptosis were independent of p53. The previous study showed that IP6 (0.25-4 mM) induced G1 arrest, and, in time kinetics, maximum G1 arrest at 24 h of treatment, which was sustained significantly up to 72 h in DU145 cells (p53min) (Singh et al., 2003). However, the G1 arrest was not observed in our study when cells were treated with IP6, which could be due to the use of different types of cancer cell lines. Although cell doubling time of PC3 and DU145 is shown about 40 h without significant difference between two cell lines (Diallo et al., 2006), the previous study showed different patterns of cell cycle alteration by the addition of selenium (Venkateswaran et al., 2002). In addition, PC3 cells are androgen-insensitive cells. A recent study showed that prostate cancer cells that did not express the androgen receptor were more sensitive to the effects of IP6 on cellular metabolism as well as apoptosis (Diallo et al., 2006). Therefore, the molecular mechanism of IP6 may be different in cancer cells representative of different malignancy grades and these differences might be explained by the distinct profile of steroid receptors present in various cell lines.

Taken together, the data presented in this work indicate that IP6 induces caspase-3-mediated apoptosis and p21-mediated cell cycle regulation. Although we observed synergistic inhibition of cell growth by IP6 and MI co-treatment, we could not observe differences in the regulation of cell cycle phase distribution as well as apoptosis by the addition of MI to IP6. Therefore, further studies regarding inhibitory effect by IP6 and MI co-treatment on tumor cell differentiation and tumor marker expression need to be investigated.
