Photoelectrocatalytic decolorization of methylene blue (MB) in the presence of two types of carbon nanotube/titania and yttrium-treated carbon nanotube/titania electrodes in aqueous solutions were studied under visible light. The prepared composite electrodes were characterized by X-ray diffraction, transmission and scanning electron microscopy, energy dispersive X-ray analysis, and photoelectrocatalytic activity. The photoelectrocatalytic performances of the supported catalysts were evaluated for the decolorization of MB solution under visible light irradiation. The results showed that yttrium incorporation enhanced the decolorization rate of MB. It was found that the photoelectrocatalytic degradation of a MB solution could be attributed to the combined effects caused by the photo-degradation of titania, the electron assistance of carbon nanotube network, the enhancement of yttrium and a function of the applied potential. The repeatability of photocatalytic activity was also tested. The presence of yttrium enhanced the hydrophillicity of yttrium-carbon nanotubes/titania electrode because more OH groups can be adsorbed on the surface.

Key Words: Yttrium-carbon nanotuble/titania, Electrode, Photoelectrocatalytic, Methylene blue, Visible light

Introduction

Titanium dioxide (TiO2)-induced photocatalysis is an established advanced oxidation process for the treatment of contaminated aqueous and gaseous streams. However, poor adsorption capacity, formation of rapid aggregates in a suspension and also recycling difficulties restricted the utilization of bare TiO2. Moreover, it can be excited only under illumination with UV light at wavelengths below 400 nm because of the large band gap (3.2 eV) for anatase TiO2. Unfortunately, only ca. 4% of the solar radiation that reaches the Earth’s surface exists in the UV region; indeed, more than 45% lies in the visible region. Therefore, in practical applications, attempts have been made to support TiO2 nanoparticles on porous adsorbent materials and to extend the light absorption of the photocatalysts to the visible region.

Among these materials, carbon nanotubes (CNTs) have attracted much attention and have become a very active field of research. CNTs, as a new class of nanomaterials, have been drawn to considerable attention for their applications as catalyst supports owing to their unique electrical properties, high chemical stability and high surface-to-volume ratio. Moreover, CNTs have a variety of electronic properties. They may also exhibit metallic conductivity as one of the many possible electronic structures. CNTs have a large electron-storage capacity (one electron for every 32 carbon atoms),16 the ability of CNT can promote the electron-transfer reactions at carbon nanotubes modified electrodes.

On the other side, previous works have also emphasized that photocatalytic (PC) activity of TiO2 can be improved by doping of TiO2 with transition metals. The study of Choi15 studied 21 transition metal ions doped TiO2 and found that when Fe3+, Mo6+, Ru3+, Os8+, Re9+, V5+ and Rh7+ were used at 0.1 - 0.5%, a significant increase in the photo-reactivity of TiO2 samples was achieved for both chloroform oxidation and reduction. In the review of Fox and Dulay,16 oxidation states of elements were found to be important in a way that both trivalent and pentavalent ions behave as recombination centers for electron-hole pairs. Recently, it has been also demonstrated that the presence of heavy metals such as Pd, Au and Ag on TiO2 can enhance the degradation efficiency of PC reactions. Rare earth ions (La3+, Eu3+, Sm3+, Nd3+, Pr3+) doped TiO2 catalysts has also attracted much attention in PC processes owing to their high PC activities in the degradation of organic molecules. A recent study investigated the photoactivity of yttrium incorporated TiO2 supported ZSM-5 catalysts. Yttrium incorporation enhanced the decolorization rate percentage of methyl orange. Lin and Yu reported the PC activities of mixtures of TiO2 with Y2O3. Their results revealed that mixtures of TiO2 with Y2O3 (0.5 wt %) induce higher photoactivity than pure TiO2 for the oxidation of acetone. In the study of Ismail,24 Y2O3 particles were embedded into Fe2O3/TiO2 mixed oxides by sol-gel method. This ternary mixed oxide resulted in a higher photooxidation rate for EDTA than pure TiO2.

On the basis of these studies, we have attempted to prepare novel PC materials. This involves TiO2 loading on the surface of CNTs modified by Y3+ ions, which, to the best of our knowledge, was not reported before. To explore the synergism induced after TiO2 and Y2O3 nanoparticles are adsorbed on the CNTs surface, as prepared photocatalysts have been examined by using X-ray diffraction (XRD), surface area (BET) measurements, scanning electron microscopy (SEM) with energy dispersive X-ray analysis (EDX) techniques, and transmission electron microscopy (TEM). Performances of these new materials are tested for the PC decolorization of methylene blue (MB, C16H18N3S·Cl·3H2O) under visible light illumination. MB is a
water-soluble azo dye, produced in textile, printing, paper manufacturing, and pulp processing and pharmaceutical industries. It is a major water pollutant in these industries and release into the environment create real problems. It was selected because under anaerobic conditions it has the potential to produce more hazardous aromatic amines. Thus, MB is selected as the probe molecule in this study and its decolorization is controlled under the effect of yttrium ion content. Besides, recycling studies are performed to test the repeatability of the photocatalysts, and the hydrophilicity of the electrodes was also studied.

Experimental

Materials. Carbon nanotubes (CNTs) were selected as the support material. The CNTs (Multiwall nanotubes, diameter: ~20 nm, length: ~5 µm) were supplied from Carbon Nano-Material Technology Co., Ltd, Korea and used without further purification. The TNB (Ti(O2C2H4)3) as a titanium source for the preparation of composites was purchased from Acros Organics, New Jersey, USA. For the oxidation of the surface of the CNT, m-chloroperbenzoic acid (MCPBA) was used as an oxidized reagent; also purchased from Acros Organics, New Jersey, USA. Methylene blue was the analytical grade chemical and reagent; also purchased from Acros Organics, New Jersey, USA. For the oxidization of the surface of the CNT, preparation of composites was purchased from Acros Organics, New Jersey, USA. Methylene blue was the analytical grade chemical and purchased from Duksan Pure Chemical Co., Ltd, Korea. Benzene (99.5%) was used as an organic solvent which was purchased from Duksan Pure Chemical Co., Ltd, Korea. Yttrium nitrate hexahydrate (Y(NO3)3·6H2O) was obtained from Daejung Chemicals & Metals Co., Ltd, Korea. The novolac typed polymer resin (PR) was supplied from Kangnam Chemical Co., Ltd, Korea. Reagent-grade solvents, benzene and ethyl alcohol, were purchased from Dukas Pure Chemical Co. and Daejung Chemical Co., Korea and used without further purification.

Preparation of Y-CNT composites. To begin preparing this experiment, the 2.0 g MCPBA as oxidizing agent was melted in 60 mL benzene. Then 0.6 g CNTs was put into the oxidizing agent, refluxed for 6 h, filtered and dried. The oxidized CNTs were added to nitrate solution containing Y(NO3)3·6H2O, of various concentration, and then the solutions were homogenized under reflux at 343 K for 2 h using a magnetic stirrer in a vial. After being heat treated at 773K for 1 h with a heating rate of 279 K/min, the Y treated CNT composites were obtained.

Preparation of Y-CNT/TiO2 composite electrodes. The Y treated CNT composites were put into the mixing solution of TNB and benzene with a volume ratio of 4:16. Then the solutions were homogenized under reflux at 343 K for 5 h, while being stirred in a vial again. After stirred, the solutions transformed into Y-CNT/TiO2 gels, and these gels were heat treated at 973 K for 1 h with a heating rate of 279 K/min. After cooling, the Y-CNT/TiO2 composites were obtained. Result 0.4 g PR was added to the Y-CNT/TiO2 composites, and the composites were pressed at a pressure of 250 kg/cm2 in a mould with dimensions of 9.95 mm × 39.5 mm × 5.95 mm. The mixture was then heat treated at 673 K for 1 h. After cooling, the Y-CNT/TiO2 composite electrodes were obtained. The preparation conditions and the nomenclatures of the samples are showed in Fig. 1 and Table 1.

Characterization of the Y-CNT/TiO2 composites. XRD technique was used for crystal phase identification and estimation of the anastase-to-rutile ratio. XRD patterns were obtained at room temperature with a diffractometer Shimata XD-D1 (Japan) using Cu Kα radiation. SEM was used to observe the surface state and porous structure of the Y-CNT/TiO2 composites using a scanning electron microscope (JOEL, JSM-5200, Japan). EDX spectroscopy was used to measure the elemental analysis of the Y-CNT/TiO2 composites. TEM (JEOL, JEM-2010, Japan) at an acceleration voltage of 200kV was used to investigate the size and distribution of the yttrium and titanium deposits on the CNT surface of various samples. TEM specimens were prepared by placing a few drops of the sample solution on a carbon grid. In order to test the hydrophilicity of the YCT series electrodes, the time of complete wetting for a drop of MB solution on the surface of electrode was determined. The hydrophilicity of the electrodes was studied in terms of the size of wetting measurement by a sessile drop method using a camera (SOKDSC-T700, SONY).

Photoelectrocatalytic (PEC) decolorization of MB. The PEC decolorization was performed by using Y-CNT/TiO2 electrodes in a 100 mL glass container and then irradiating the system with visible light (8W, KLD-08L/P/N, FAWOO TECHNOLOGY), which was used at the distance of 100 mm from the solution in darkness box. Prior to illumination, the electrode was impregnated in the pristine MB solution in the dark for 30 min needed to achieve adsorption/desorption equilibriuim. The counter electrode was artificial graphite (TCK, Korea), which dimension was 9.95 mm × 39.5 mm × 5.95 mm. The Y-CNT/TiO2 elec-
trodes were placed in 50 mL of $1.0 \times 10^{-5}$ mol/L MB solution. The PEC degradation of MB was performed with voltage of 6.0 V and visible light (Fig. 2). The PEC activities of Y-CNT/TiO$_2$ electrodes were investigated using the PEC rate of MB solution, which was measured as function of time. The blue color of the solution faded gradually with time due to the adsorption and degradation of MB solution. And then the concentration of MB in the solution was determined as a function of irradiation time from the absorbance change at a wavelength of 660 nm. The decolorization rate of MB was calculated by the following equation:

$$\text{Decolorization} \% = \frac{(C_0 - C)}{C_0} \times 100\%$$

Where $C_0$ is the initial concentration of MB and C is the concentration of MB after “t” minutes visible light irradiation.

### Results and Discussion

**Structure and morphology of Y-CNT/TiO$_2$ composites.** The values of BET surface areas of Y-CNT/TiO$_2$ composites are shown in Table 2. As shown in Table 2, the BET surface area of non-yttrium treated CNT/TiO$_2$ was 198, while the BET surface areas of yttrium treated CNT/TiO$_2$ composites decreased gradually from 172 to 119 m$^2$/g with an increase of Y(NO$_3$)$_3$ concentration. At the same addition of TNB, it was thought that the intensity of the Y particle aggregation increased with the increase of Y(NO$_3$)$_3$ concentration. These particles were heavily agglomerated to gather into a blocky-shaped particle. These results can be seen clearly from SEM images obtained from powder Y-CNT/TiO$_2$ composites. The results showed that there is a decrease in the BET surface area of the Y-CNT/TiO$_2$ composites after formation of Y particles by Y(NO$_3$)$_3$ treatment. This was suggested that some porosity was developed during the heat treatment. It was thought that the composites are nano materials that include a lot of micropores. It was thought that there are two possible reasons. First, it could be attributed to the micropores being partly blocked by the formation of Y particles on the CNT/TiO$_2$ surface during heat treatment. Second, the BET surface area decreased due to the curing of polymer resin with heat treatment, which blocked the micropores and formed some new mesopores. It was possible that the phenol resin had coated some CNT/TiO$_2$ particles to form some larger composite particles during the curing process. As expected, the BET surface area is thought to decrease due to the blocking of the micropores by surface complexes introduced through the formation of Y-CNT/TiO$_2$ composites.

The XRD results for the catalyst samples are shown in Fig. 3. The structure of the non yttrium treated CNT/TiO$_2$ composites (YCT0) showed a mix of anatase and rutile crystals. It is well known that the crystal structure of the titanium dioxide is mainly determined by the heat treated temperature. The peaks at 25.3, 37.8, 48.0 and 62.5° (2$\theta$) are the diffractions of (101), (004), (200) and (204) planes of anatase, indicating the developed CNT/TiO$_2$ composites existed in an anatase state. The peaks at 27.4, 36.1, 41.2 and 54.3° (2$\theta$) belong to the diffraction peaks of (110), (101), (111) and (211) of rutile. Therefore, it can be concluded that the developed CNT/TiO$_2$ composites had a mixing structure of anatase and rutile crystals when annealed at 973 K. According to the published paper, if the anatase phase is

formed below 773 K, it starts to transformed into a rutile-type structure above 873 K, and then changes into a single phase of rutile at 973 K ~ 1173 K.25 We have previously demonstrated that the crystallization phenomena in C/TiO2 composites that are heat treated at 973K results in a mixed anatase-rutile structure.26 Thus The XRD result obtained here is reasonable.

In the XRD patterns of Y-CNT/TiO2 samples, formation of Y2O3 is searched owing to the variation of rare earth salt into rare earth oxides during the calcinations process. Although it is not clearly observable in Fig. 3, a new reflection at 29.2° (2θ) emerges and indicates characteristic (222) diffraction of Y2O3 particles. Additional Y2O3 diffractions (400), (411), (134) and (440) are obtained at 33.8, 35.9, 43.8 and 48.7° (2θ), respectively.5 Intense peaks from anatase still appeared in the Y-CNT/TiO2 composites and became broader than that of non-yttrium treated CNT/TiO2 composite with increasing concentration of the Y(NO3)3 solution. Unfortunately, these high angle diffractions are complicated and not easily detected in the figure because of the overlapping of diffraction peaks attributed to TiO2, Y2O3 and those of the CNTs support.

The micro-surface structures and morphology of the Y-CNT/TiO2 composites were characterized by SEM (Fig. 4) and TEM (Fig. 5). Fig. 4 shows the macroscopical changes in the morphology of the Y-CNT/TiO2 composites. As shown in Fig. 4, the TiO2 particles were well attached to the surface of the CNT network, and the distribution was uniform. In the report of Zhang,27 a good dispersion of small particles could provide more reactive sites for the reactants than aggregated particles. At the same time, the conductive of the CNT network can facilitate the electron transfer between the adsorbed dye molecules and the catalyser substrate.28 It was beneficial for the enhancement of the PC activity of these composites. Moreover, yttrium particles were fixed on the surface of the CNT network in small clusters, and the distribution was not uniform. Moreover, we could not find the difference of the intensity of aggregation increased with the increase of Y(NO3)3 concentrations. These particles were heavily agglomerated to form blocky-shaped particle, and these results can be seen clearly in Fig. 4(b) to Fig. 4(d). These results are also confirmed by TEM inspection of the Y-CNT/TiO2 composites. As shown in Fig. 5, for the CNT/TiO2 composites, the TiO2 particles were distributed uniformly outside surface of CNT tube; for the Y-CNT/TiO2 composites, the TiO2 particles were still distributed uniformly outside surface of CNT tube, Y particles were completely attached on the surface of the tube although this caused partial agglomeration to form blocky-shaped particle. However, in most cases, due to the capillary effect,29-30 Y particles were formed outside the tubes, leading to poor synergic effect of the Y-CNT/TiO2 composites.

Fig. 6 shows the EDX spectra of Y-CNT/TiO2 composites prepared. From the EDX data, the main elements such as C, O, Ti and Y existed. The results of the EDX elemental microanalysis of the Y-CNT/TiO2 composites are listed in Table 3. The contents of the yttrium component for YCT1, YCT 2, YCT 3 and YCT 4 are 0.9, 1.5, 1.8 and 2.1%, respectively. It can be expected that the contents of the yttrium component in the composites increased with an increase of Y(NO3)3 concentrations.

Figure 7. Effect of the photoelectrocatalytic decolorization rate of MB for different Y-CNT/TiO₂ composite electrodes: (a) under visible light irradiation, (b) in a function of the applied potential of 6.0V under visible light irradiation.

The electrodes under visible light irradiation with or without electron currents. Here we discussed three kinds of degradation processes: 1). PEC: Visible light irradiation using the electrodes with a potential of 6.0V; 2). PC: Visible light irradiation using the electrodes; 3). P: Only visible light irradiation. From the results presented in Fig. 7, comparing with CNT/TiO₂ and Y-CNT/TiO₂ composite electrodes, except YCT4, the PEC and PC effects of the Y treated CNT/TiO₂ composite electrodes were all better than that of non-Y treated CNT/TiO₂ in the irradiation time of 60 minutes. It was implied that the introduction of Y enhanced the PEC and PC degradation of MB solution. However, for the Y treated CNT/TiO₂ series, the PEC and PC degradation efficiency of the sample YCT2 is higher than that of the other samples in the irradiation time of 60 minutes. The electrocatalytic activity of Y particles for this reaction is dependent on various factors, which involves the size and dispersion of the particles, supporting materials and their surface conditions. In the case of YCT3 and YCT4, the Y particles were heavily agglomerated to gather into a blocky-shaped particle (see Fig.4 (d) and (e)), which leads to the significant reduction on its activity. It is well known that
The PEC activity will increase with an increase of Y content in a certain range. At the same time, the morphology of Y in the Y-CNT/TiO₂ composites is an important factor. Note that the optimization of PEC decolorization of MB using Y-CNT/TiO₂ composite electrodes will be studied in detail in another paper.

**The repeatability of photoelectrocatalyst activity.** To examine the stability of YCT2 electrode, recycling experiments are carried out (Fig. 8). For each new cycle, the photoelectrocatalyst is washed and calcined at 400 °C for 1 h by keeping other reaction conditions constant. After five cycles, the decolorization rate decreases only approximately 9%, from 56 to 47%. This indicates that the PEC activity of YCT2 electrode has repeatability. Similar results are obtained in system of yttrium incorporated TiO₂ supported ZSM-5. The reduction in the decolorization rate among the cycles may be explained by the formation of by-products and their accumulation in the cavities and on the active surface sites of the electrode. It was thought that the result was due to the decrease of the electrode surface for both photon absorption and MB adsorption.

**Visible light photo-induced hydrophilicity.** In order to test the hydrophilicity of the YCT series electrodes, the time of complete wetting for a drop of MB solution on the surface of electrode was determined. If the time of complete wetting is short this means good wetting and the contact angle lower, which is good hydrophilicity. Changes of the MB solution complete wetting on the surface of Y-CNT/TiO₂ electrodes, induced by SW visible light irradiation, are shown in Fig. 9. Indoor condition, the time of complete wetting for non yttrium treated CNT/TiO₂ electrode is about 8 minutes. It reduces with adding of yttrium and approaches 30 seconds for YCT2. However under visible light irradiation, the time of complete wetting falls from 8 to 6.5 minutes and from 5.5 to 3.5 minutes for YCT0 and YCT4, respectively. The time of complete wetting changes slightly for other electrodes due to the original times are lower. The results showed that YCT1, YCT2 and YCT3 have good hydrophilicity indoor or under visible light irradiation. It was considered that the mechanism of hydrophilicity is different from PC activity, the electrons and holes are still produced but they react differently. The electrons tend to reduce the Ti (IV) cations to Ti (III) state; the electrons and holes are still produced but they react differently. The reduction in the decolorization rate among the cycles may be explained by the formation of by-products and their accumulation in the cavities and on the active surface sites of the electrode. It was thought that the result was due to the decrease of the electrode surface for both photon absorption and MB adsorption.

While holes remaining at the valence band of TiO₂, thereby initiating the process for oxygen removal and hence hydrophilicity of the electrode.

**Conclusion**

In this study, we presented the fabrication and characterization of CNT/TiO₂ and Y-CNT/TiO₂ composite electrodes. The BET surface area of Y-CNT/TiO₂ composites decreased with an increase of Y component. XRD data revealed that the structure for the Y-CNT/TiO₂ composites showed a single anatase crystal phase. The TEM microphotographs of CNT/TiO₂ and Y-CNT/TiO₂ composites showed that TiO₂ particles were distributed uniformly in the CNTs network, and the Y particles were fixed on the surface of the CNTs, although they were partly aggregated. From the EDX data, the main elements such as C, O, Ti and Y existed. The Y-CNT/TiO₂ samples have a higher PEC and PC degradation efficiency than that of the non-Y treated CNT/TiO₂ sample. The results demonstrated that the PEC degradation of MB solution could be attributed to synergetic effects of the photo-degradation of TiO₂, the electron asis-
Photoelectrocatalytic Properties of Y-CNT/TiO₂

The enhancement of Y and a function of the applied potential. The morphology of Y in the Y-CNT/TiO₂ composites is an important factor. A loss of the catalytic activity (9% in 60 minutes) of YCT2 electrode was found after its first use. Hydrophilicity and photoactivity arise due to two different mechanisms, but they go side by side i.e. if one increases the other also increases or vice versa, this is due to interfacial nature of the two processes.
