Chemotherapy-induced side effects affect the quality of life and efficacy of treatment of cancer patients. Current approaches for treating the side effects of chemotherapy are poorly effective and may cause numerous harmful side effects. Therefore, developing new and effective drugs derived from natural non-toxic compounds for the treatment of chemotherapy-induced side effects is necessary. Experiments in vivo and in vitro indicate that Panax ginseng (PG) and its ginsenosides are undoubtedly non-toxic and effective options for the treatment of chemotherapy-induced side effects, such as nephrotoxicity, hepatotoxicity, cardiotoxicity, immunotoxicity, and hematopoietic inhibition. The mechanism focus on anti-oxidation, anti-inflammation, and anti-apoptosis, as well as the modulation of signaling pathways, such as nuclear factor erythroid-2-related factor 2 (Nrf2)/heme oxygenase-1 (HO-1), P62/keap1/Nrf2, c-jun N-terminal kinase (JNK)/p38 caspase 3, mitogen-activated protein kinase protein (MEK)/extracellular signal-regulated kinases (ERK), AMP-activated protein kinase (AMPK)/mammalian target of rapamycin (mTOR), mitogen-activated protein kinase protein kinase 4 (MKK4)/JNK, and phosphatidylinositol 3-kinase (PI3K)/AKT. Since a systemic review of the effect and mechanism of PG and its ginsenosides on chemotherapy-induced side effects has not yet been published, we provide a comprehensive summarization with this aim and shed light on the future research of PG.

1. Introduction

As an effective strategy to treat cancer, chemotherapy is widely applied in the treatment of tumors that have a tendency for systemic spread and middle and advanced metastatic tumors. However, chemotherapeutic drugs are considered to be a high-risk treatment because of the narrow dose range of treatments that offer the maximum benefit with minimum severe side effects [1]. Among these chemotherapeutic drugs, cisplatin (CP), 5-fluorouracil (5-Fu), cyclophosphamide (CY), and Adriamycin (ADM) are commonly used but can cause several adverse reactions. According to the incidence of these adverse reactions, the decreasing order of incidence is nephrotoxicity, gastrointestinal mucosal injury, neurotoxicity, hematopoiesis inhibition, cardiotoxicity, immunosuppression, hepatotoxicity, and hair loss [2–8]. These side effects result from drug-derived damage to human tissues, cells, and the regulation of multiple targets and signaling pathways. The mechanisms behind these side effects focus on oxidative stress, inflammation, apoptosis, and autophagy.

Although some Western medicines can reduce the side effects of chemotherapy, their limitations are often ignored. For example, amifostine can ameliorate cumulative myelotoxicity, acute and chronic neutropenia, and/or thrombocytopenia induced by CY, but it can lead to adverse reactions such as dizziness and vomiting [9]. Additionally, mannitol and furosemide do not significantly relieve CP-induced nephrotoxicity, and patients will still be troubled by nephrotoxicity [10]. Hence, discovering non-toxic and effective drugs from ethnic or natural medicine is important.

In Eastern countries, side effects induced by chemotherapy are considered to be a deficiency syndrome of the human body. The treatment of deficiency disease often requires the use of tonic medicine. Among them, Panax ginseng (PG), usually refers to the dried root and rhizome of PG CA Meyer of the family Araliaceae, is regarded as a typical tonic medicine and has a long history of use in China, Korea, and Japan. Recently, clinical studies have shown that compounds or medicines containing different forms of PG have a promising effect on side effects caused by chemotherapy [11,12]. Moreover, ginsenosides, which are the main active ingredient of PG, have a pivotal role in the pharmacological actions of PG. Shenyi capsules, which is a Chinese patented drug that comprised ginsenoside Rg3, could effectively attenuate the side effects induced by chemotherapy in patients, such as nausea and vomiting [13]. Meta-analysis revealed that ginsenoside Rg3 alone reduced chemotherapy-induced myelosuppression in clinic [14]. Thus, scientists all over the world have given attention to the ameliorative effects of PG and its ginsenosides on the side effects caused by chemotherapy and have accumulated considerable discoveries. However, the pharmacological actions and potential mechanisms of PG and its ginsenosides on chemotherapy-induced side effects have not been systematically summarized.

This article reviews the medicinal potential and underlying mechanism of PG and its ginsenosides on the adverse reactions of chemotherapy and puts forward the view that PG and its ginsenosides can be used as adjuvants to reduce the side effects of chemotherapy. We hope this review will lay the foundation for an in-depth investigation of the biochemical mechanisms and pharmacological properties of PG and its ginsenosides to derive benefits from the further development and utilization of PG in treating the side effects of chemotherapy.

2. Different types of PG and its ginsenosides

According to different processing techniques, PG can be developed into several types, including white ginseng, red ginseng, and black ginseng (which is also called black-red ginseng). White ginseng is the product obtained from peeled and naturally dried PG. Red ginseng is obtained by steaming PG once. Black ginseng is the product generated by steaming PG nine times [15].

Ginsenosides are dammarane triterpenoid saponins and are composed of 17 carbons. Protopanaxadiol (PPD) and protopanaxatriol (PPT) are aglycones that have been isolated from PG. According to the number of hydroxyl groups in aglycone components, dammarane saponins are composed of two species, namely, the PPD type and the PPT type. Common PPD type ginsenosides are Rg3, Rb1, Rd, Rb3, Rh2, and compound K (CK), whereas PPT type ginsenosides are Re and Rg1.

3. Effects of PG and its ginsenosides on chemotherapy-induced side effects

3.1. Effects of PG on chemotherapy-induced nephrotoxicity

Nephrotoxicity is a common side effect of chemotherapy and ultimately impacts the therapeutic efficacy of chemotherapy treatment of cancer patients. Studies have revealed that 90% of cancer patients receiving chemotherapy suffer from nephrotoxicity [2]. For example, CP, CY, 5-Fu, and ADM may lead to serious nephrotoxicity, including tubular damage and renal failure [16]. Among them, CP exhibits the strongest nephrotoxicity [17]. The pathogenic mechanism of chemotherapy-induced nephrotoxicity includes oxidative stress damage, cell apoptosis, and inflammation. Presently, PG and its ginsenosides can reduce levels of blood urea nitrogen and creatinine, thus promoting the recovery of the renal function and subsequently reducing kidney damage [18,19]. Therefore, PG and its ginsenosides are potential drugs for the treatment of CP-induced nephrotoxicity (Table 1).

3.1.1. Chemotherapy-induced nephrotoxicity

Nephrotoxicity is a common side effect of chemotherapy and ultimately impacts the therapeutic efficacy of chemotherapy treatment of cancer patients. Studies have revealed that 90% of cancer patients receiving chemotherapy suffer from nephrotoxicity [2]. For example, CP, CY, 5-Fu, and ADM may lead to serious nephrotoxicity, including tubular damage and renal failure [16]. Among them, CP exhibits the strongest nephrotoxicity [17]. The pathogenic mechanism of chemotherapy-induced nephrotoxicity includes oxidative stress damage, cell apoptosis, and inflammation. Presently, PG and its ginsenosides can reduce levels of blood urea nitrogen and creatinine, thus promoting the recovery of the renal function and subsequently reducing kidney damage [18,19]. Therefore, PG and its ginsenosides are potential drugs for the treatment of CP-induced nephrotoxicity (Table 1).

3.1.2. Anti-oxidative effect of PG and ginsenosides on chemotherapy-induced nephrotoxicity

Several studies showed that anti-oxidative effects have partially contributed to the protection of PG and its ginsenosides against CP-induced nephrotoxicity. First, ginsenosides attenuate CP-induced nephrotoxicity by directly reducing the excessive production of reactive oxygen species (ROS) or indirectly alleviating the excessive production of ROS via inhibiting levels of Cytochrome P450 E1 (CYP2E1) and HO-1. Ginsenoside Rk3 and Rh4, which are different isomers at the double bond positions (D20e21 and D20e22), possessed similar renoprotective effects against the cytoxicity of CP in cultured renal tubular cells, which was characterized by a reduction of lactate dehydrogenase and an increase in cell viability [18]. In CP-treated porcine renal proximal epithelial tubular (LLC-PK1) cells, the mixture of ginsenosides Rk3 and Rh4 (KG-KH) increased cell viability and decreased ROS production [20]. Interestingly, in CP-treated male ICR mice, ginsenosides Re and Rg5 played an anti-oxidative role by reducing CYP2E1 level and thus down-regulating the ROS level [19,21]. Additionally, the over-expression of HO-1 is one of the causes of excessive ROS production. Ginsenoside Rh2 could partly reduce CP-induced nephrotoxicity by down-regulating CYP2E1 and HO-1 levels [22]. Moreover, ginsenoside Rg3 could reduce the excessive production of ROS by decreasing the level of HO-1/NAD (P) 4 quinone oxido-reductase (NQO)-1 mediated by Nrf2, thus protecting CP-treated LLC-PK1 cells [23]. Second, the renoprotective effect of PG and its ginsenosides was achieved by increasing the activity of antioxidant enzymes and inhibiting lipid peroxidation. For example, Yousef et al. found that the activities of superoxide dismutase, catalase, glutathione S-transferase, glutathione peroxidase, ATPase, and renal non-enzymatic antioxidant glutathione were increased by PG in CP-treated rats. Furthermore, PG decreased the levels of renal

thiobarbituric acid reactive substances, xanthine oxidase, and nitric oxide [24]. Moreover, ginsenosides can reduce the nephrotoxicity induced by chemotherapy by recovering the levels of antioxidant enzymes and suppressing lipid peroxidation. Ginsenosides such as ginsenoside Rg5, Rh2, Rg3, Rd, and KG-KH also increased antioxidant enzyme levels and consequently attenuated CP-induced renal damage [21–23,25]. Additionally, ginsenosides Re, Rg5, Rh2, and Rd inhibited the excessive production of CP-induced lipid peroxidation products, such as 4-hydroxyynonenal and malonaldehyde (MDA), in vivo.

3.1.3. Anti-apoptotic and anti-inflammatory effects of PG and ginsenosides on chemotherapy-induced nephrotoxicity

PG and its ginsenosides attenuate CP-induced nephrotoxicity by producing an anti-apoptotic effect. Initially, PG and its ginsenosides inhibit apoptosis mainly by regulating the related factors of the endogenous apoptosis pathway. PG improved nephrotoxicity by reducing P53 activity and DNA fragmentation while inducing DNA repair in CP-treated rats [25]. Next, ginseng Rd inhibited DNA fragmentation in CP-treated LLC-PK1 cells [26]. Moreover, Qi et al. studied the anti-apoptotic properties of ginsenoside Rh2 by systematically assessing its effects on the generation of a pro-apoptotic mediator induced by CP in ICR mice [22]. They found that ginsenoside Rh2 attenuated pro-apoptotic mediator production and enhanced the Bcl-2 level in ICR mice. Similarly, the anti-apoptotic effect of ginsenoside Rk1 included reducing the level of pro-apoptotic factors and increasing the Bcl-2 level in CP-treated HEK-293 cells [27]. Other ginsenosides, such as ginsenoside Re and Rg5, also exhibited an anti-apoptotic effect by adjusting the levels of Bcl-2 and Bax [19,21]. Second, the anti-apoptotic mechanisms of ginsenosides are related to the modulation of JNK-related pathways. Recently, studies have reported that fermented black ginseng and its active component ginsenoside 20(S)-Rg3 can reduce CP-induced oxidative cytotoxicity by decreasing the protein levels of phosphorylated JNK, P53, and cleaved caspase-3, which might lead to a blockage of the JNK/P53/caspase-3 signaling cascade in LLC-PK1 cells [28]. Similarly, in CP-induced LLC-PK1 cells, microwave-processed ginseng, and its ginsenosides also alleviated cell damage by cisplatin by decreasing the expressions of P53, JNK, and caspase-3 [29]. Notably, Lee et al. [30] compared the action of ginsenoside Rh3 and its positional double bond isomer ginsenoside Rk2 in CP-induced apoptotic damage and found that ginsenoside Rh3 elicited a better protective effect than ginsenoside Rk2. Furthermore, ginsenoside Rh3 protected kidney cells from apoptotic damage by inhibiting the JNK and ERK signaling pathways, which was evidenced by decreases in the levels of JNK, ERK, p38, and cleaved caspase-3. Meanwhile, autophagy is the key pathway of CP-induced nephrotoxicity. A current study by Xing et al. claimed that suppression of autophagy led to apoptotic inactivation, which suggests that autophagy acted adversely in the kidney injury model for CP [31]. Further research reported that ginsenoside Rh3 inhibited autophagy through the AMPK/mTOR-dependent signaling pathway in CP-treated mice. Furthermore, ginsenoside Rh3 suppressed cell apoptosis and autophagy by inactivating the AMPK signaling pathway in HEK293 cells.

Moreover, the anti-inflammatory effects of ginsenosides alleviated CP-induced nephrotoxicity to some extent. In CP-treated rats, ginsenoside Rh2 elicited anti-inflammatory effects, which were manifested as decreased expressions of TNF-α, NF-kB, inducible nitric oxide synthase, and cyclooxygenase 2 [22]. What’s more, ginsenoside Rg5 [21] and Re [19] exerted the same anti-inflammatory effects by inhibiting the generation of pro-inflammatory cytokines and inflammation-related enzymes.

3.2. Effect of PG on chemotherapy-induced gastrointestinal mucosa injury

3.2.1. Chemotherapy-induced gastrointestinal mucosa injury

Gastrointestinal mucosal injury is a common side effect induced by chemotherapy. For example, vomiting after chemotherapy may be associated with gastric mucosal damage, which appears in 90% of patients receiving chemotherapy [3]. Diarrhea associated with intestinal mucosal damage also affects the progress of chemotherapy, with an incidence rate of 50% to 80% of patients receiving chemotherapy (e.g., 5-Fu) [4]. Moreover, oral mucositis is one of the common complications of chemotherapy, which often occurs in 18% to 40% of patients in the first stage of chemotherapy [5]. Generally, adverse reactions caused by gastrointestinal mucosal injury have a higher incidence rate. Overall, PG and its ginsenosides have exhibited promising therapeutic effects on the above-mentioned adverse reactions.

3.2.2. Therapeutic effect of PG and ginsenosides on chemotherapy-induced hamster oral mucositis and diarrhea

In one study, ginsenoside Rb1 was contained in the chitosan–sodium alginate membrane (G-Rb1film) and applied to 5-Fu-induced hamster oral mucositis. The results revealed that the G-Rb1film had a curative effect and anti-inflammatory properties in chemotherapy-induced severe oral mucositis [32]. In 5-Fu-induced oral mucositis hamsters, ginsenoside Rb1 reduced the mucositis area and alleviated inflammatory cell infiltration, myeloperoxidase activity, ulceration, and abscess formation.

Additionally, our study has revealed that Shenzhu Capsule, which contains PG total saponins (PGS), PG polysaccharides, Atractylodes macrocephala volatile oil (AMO), and Atractylodes macrocephala polysaccharides (AMP), alleviated diarrhea effectively in 5-Fu-treated mice [33]. It reversed colonic histopathological changes, restored the overall structure of the intestinal microflora, and inhibited potential pathogens that might be related to diarrhea. PGS combined with AMO, not AMO or PGS alone, could also improve diarrhea caused by 5-Fu. The mechanism was related to the inhibition of intestinal inflammatory cytokines caused by chemotherapy and a reduction of potential pathogens, indicating that together with AMO, ginsenosides separated from PG might have the potential to treat diarrhea caused by chemotherapy [34].

3.3. Effects of PG on chemotherapy-induced neurotoxicity

3.3.1. Chemotherapy-induced neurotoxicity

Chemotherapy is a systemic treatment strategy, and its side effects are distributed throughout the body. Among these side effects, the nervous system is the main target of chemotherapy-induced side effects, and 50% of cancer patients receiving chemotherapy suffer from neurological side effects, such as neuropathic pain and cognitive impairment [6]. Further, PG and its ginsenosides have significant potential therapeutic effects on chemotherapy-induced adverse neurological reactions.

3.3.2. Therapeutic effect of PG and ginsenosides on chemotherapy-induced neuropathic pain

Oxaliplatin is widely used due to its promising anticancer effects. However, it often causes peripheral neuropathy, including cold and mechanical hyperalgesia. Therefore, Suzuki et al. evaluated the in vivo effect of PG on neuropathic pain induced by oxaliplatin in rats and found that PG reduced the increase of cold allodynia and mechanical hyperalgesia [35]. They also found that the PG extract exhibited a preventive effect in L–OH–treated differentiated PC12 cells and claimed that the most active
component of PG was ginsenoside F2 [36]. Similarly, in murine primary dorsal root ganglia cells, they found that PG exhibited a protective effect on neuronal injury, and its main active component was ginsenoside Rg3.

3.3.3. Therapeutic effect of PG and ginsenosides on chemotherapy-induced cognitive impairment

Ginsenosides significantly affected chemotherapy-induced cognitive impairment. In CP-treated rats, Chen et al. [37] found that ginsenoside Rb1 could significantly improve cognitive impairment and neuronal loss by suppressing oxidative stress and hippocampal neuronal inflammation and recovering the cholinergic neuron function. Furthermore, ginsenoside Rg1 could prevent cognitive impairment caused by chemotherapy, which might be correlated with the regulation of microglia-related cytokines and mediators, protection of neuronal activity, promotion of neural plasticity in specific brain regions related to cognitive processing, and inhibition of neuroinflammation [38]. Shi et al. developed a chemo brain mouse model with a combination of three doses of docetaxel, doxorubicin, and cyclophosphamide (DAC) at 2 day intervals and found that after the administration of ginsenoside Rg1, the decrease of prefrontal and hippocampal neuronal activity induced by DAC was reversed, and the elimination of dendritic spines of cortical neurons was improved in vivo. Meanwhile, ginsenoside Rg1 suppressed microglia polarization from the M2 to M1 phenotype as well as the increase of pro-inflammatory factors, including IL-6, but up-regulated IL-4 and IL-10 while modulating cytokine mediators. In in vitro experiments, ginsenoside Rg1 also inhibited the increased levels of pro-inflammatory cytokines in BV-2 microglial cells and increased cell viability in PC12 cells.

3.4. Effects of PG on chemotherapy-induced hematopoiesis inhibition

3.4.1. Chemotherapy-induced hematopoiesis inhibition

Of all the side effects caused by chemotherapy, hematopoiesis inhibition, is a formidable problem in clinic because of its toxicity in cells. A previous study indicated that 40%–47% of patients who received chemotherapy suffered from the side effects of decreased blood and bone marrow cells [7]. Myelosuppression often affects bone marrow cell lines, causing an initial decrease in white blood cells and subsequent hematopoietic stem cell/hematopoietic progenitor cell damage [39]. In clinic, serious hematopoiesis inhibition usually induces potentially life-threatening infections. Considering the importance of natural products as major contributors to the therapeutic properties of chemoprotective agents, the potential roles of PG and its ginsenosides against chemotherapy-induced hematopoiesis inhibition were studied (Table 2).

3.4.2. Hematopoietic function regulation of PG and ginsenosides on chemotherapy-induced hematopoiesis inhibition

Accumulating evidence indicates that PG and its ginsenosides are effective in treating chemotherapy-induced myelosuppression. Attention has been given to the effect of PG on blood cells and hematopoietic function, especially hematopoietic stem cells, and hematopoietic progenitor cells. Han et al. [40] and Zhang et al. [41] reported that CY-induced myelosuppression could be greatly improved by PG. In CY-treated mice, PG could increase the amount of peripheral blood cells, bone marrow cells, bone marrow nucleated cells (BMNCs), and the spleen/thymus index. Hematopoiesis-related cytokines, such as thrombopoietin, erythropoietin, granulocyte macrophage colony-stimulating factor (GM-CSF), hematopoietic progenitors including burst-forming unit erythroid, colony-forming unit erythroid, colony-forming unit granulocyte macrophage, and colony-forming unit megakaryocyte, and the amount of G2/M and S phase cells were increased in the mice model after PG was administrated. Furthermore, when co-decocted with Ligusticum lucidum Ait or Ophiopogon japonicus, the protective action of PG against myelotoxicity was extremely enhanced. HPLC revealed that rare saponins might be effective chemical components for treating bone marrow suppression. Additionally, PG exhibited similar pharmacological activity in the 5-Fu-treated mice, which was reflected in an improvement of the hematopoietic cytokines, including colony-forming unit granulocyte macrophage and GM-CSF [42]. Furthermore, as a biological response modifier, the ginsenoside Rg3 treatment usually promoted proliferation of the total spleen and bone marrow cells and led to an increase in colony-stimulating factors, such as IL-3, GM-CSF, and thrombopoietin in CY-treated and normal mice [43]. A study performed by Wang et al. [44] illustrated that ginsenoside Rh2 resisted micronucleus formation in bone marrow polychromatic erythrocytes and reduced DNA strand breakage in white blood cells.

3.4.3. Anti-oxidative and anti-apoptotic effects of PG and ginsenosides on chemotherapy-induced hematopoiesis inhibition

The protective effects of PG against CY-induced genotoxicity contribute to its anti-oxidative and anti-apoptotic activity. Qiu and his coworkers showed that DNA damage and bone marrow cell apoptosis stimulated by CY were alleviated by the total saponins from the stem and leaf of PG. As an antioxidant agent, the total saponins from the stem and leaf of PG increased the activities of antioxidant enzyme contents in the CP-induced myelosuppressive model [45]. Similarly, the therapeutic effects of ginsenoside Rb1 and ginsenoside Rg3 on cyclophosphamide-induced myelosuppression are also related to the inhibition of DNA damage and apoptosis. Additionally, Rb1 and Rg3 each reversed the reduction of antioxidant enzyme activities and the increase of MDA content caused by CP [46,47]. Ginsenoside CK also promoted cell proliferation and differentiation and reduced the apoptosis of BMNCs through the Bcl-2/Bax and the MEK/ERK signaling pathways, which may result in reversing ginsenoside-CK-induced changes in the peripheral blood cells, BMNCs counts, hematopoiesis-related cytokines, and colony yield of hematopoietic progenitor cells in mice [48]. Meanwhile, a fraction separated from PG and was the termed panaxadiol saponins component, which contained five ginsenosides and enhanced proliferation and differentiation of hematopoietic progenitor cells in myelosuppressive mice, with an underlying mechanism mediated by the intracellular MAPK signaling pathway in bone marrow cells [49]. Han et al. compared the effects of ginsenoside Re and its secondary metabolite ginsenoside Rk3 on chemotherapy-induced myelosuppression [50]. The result indicated that, compared with ginsenoside Re, ginsenoside Rk3 more easily passed through biofilms, promoted a higher proliferation of bone marrow cells, and improved the hematopoietic function of bone marrow in CY-induced myelosuppressive mice. This was associated with the regulation of the cytokine level, normal cell cycle recovery, and prevention of BMNC apoptosis.

3.4.4. Immunogenic effect of PG and ginsenosides on chemotherapy-induced hematopoiesis inhibition

The immunogenic activity of PG is a necessary factor that is responsible for its role in myelopoiesis to some extent. Korean PG could improve the recovery of hematopoiesis by increasing cytokine release in 5-Fu-treated mice. The levels of IL-3 and GM-CSF in serum and bone marrow and the expressions of c-Kit, SCF, and IL-1 in the spleen were elevated after uptake of Korean PG. Ginsenoside Rg1 stimulated the expressions of cytokines in bone marrow cells and partially directed this effect of Korean PG. Dammarane sapogenins (DS), which was an active fraction mainly containing PPT and PPD, showed remarkable immunological action in CY-treated

mice, as evidenced by stimulated ConA-induced splenocyte proliferation, lipopolysaccharide-induced proliferation, and the hematopoiesis recovery function. Notably, reduced red blood cells, which were hardly changed by PG and its active compounds in the myelosuppressive model, could be reversed by DS [51].

3.4.5. Extramedullary hematopoiesis regulation of ginsenoside Rg1 on chemotherapy-induced hematopoiesis inhibition

Additionally, studies have demonstrated that the protective action of ginsenoside Rg1 against CY-induced myelosuppression stems from the recovery of the bone marrow hematopoietic function and alleviation of extramedullary hematopoiesis in the spleen. Xu et al. reported that, apart from the elevation of bone marrow cells and alleviation of bone marrow damage, the up-regulation of the percentage of Lin−Sca-1+c-kit+ (LSK)-positive cells in bone marrow and peripheral blood cells, as well as the percentage of lymphoid CD3++-positive cells, were observed in the in vivo model of CY treatment after ginsenoside Rg1 treatment. Furthermore, this agent also inhibited the overexpression of the calcium-sensing receptor caused by CY, which indicated the beneficial effects of ginsenoside Rg1 on hematopoietic stem cell proliferation and mobilization into the peripheral blood. However, bone marrow hematogenesis in normal mice was not altered by ginsenoside Rg1 [52]. Another study [53] revealed that, without any effects on cell apoptosis, ginsenoside Rg1 elevated the proliferative activity of c-Kit+ hematopoietic stem and progenitor cells (HSPCs) and decreased the absolute number of c-Kit+ HSPCs, which indicated that a reduction of c-Kit+ HSPCs stimulated by ginsenoside Rg1 resulted from the mobilization of HSPCs from the spleen to the bone marrow. Furthermore, ginsenoside Rg1 was proven to increase the frequency of HSPCs and LSK HSPCs, which demonstrated that the effect of ginsenoside Rg1 on CY-induced myelosuppression was reflected by the promoted proliferation of HSPCs in splenic extramedullary hematopoiesis and the migration HSPCs from the spleen to the bone marrow.

3.5. Effects of PG on chemotherapy-induced cardiotoxicity

3.5.1. Chemotherapy-induced cardiotoxicity

Cardiotoxicity is a common side effect induced by chemotherapy, which usually leads to severe heart failure and eventually cardiomyopathy. Presently, many chemotherapy drugs can cause cardiotoxicity, including ADM, paclitaxel, and CP. Among them, cardiotoxicity caused by ADM is the most prominent, and 8% to 26% of cancer patients treated with ADM suffer from cardiotoxicity, which is attributed to oxidative damage, apoptosis, autophagic death of cardiomyocytes, and, ultimately, abnormal heart function [8]. PG and its ginsenosides show obvious cardioprotective effects, such as improved electrocardiographic changes and reversing the decrease in the ejection fraction and fraction shortening induced by ADM [54]. These results indicate that PG and its ginsenosides may be candidates for the treatment of cardiotoxicity (Table 3).

3.5.2. Anti-oxidative effect of PG and ginsenosides on chemotherapy-induced cardiotoxicity

The anti-oxidative effects of PG and its ginsenosides are responsible for their cardioprotective effect. First, the anti-oxidative effect of ginsenosides is manifested by reducing the overproduction of ROS. Wang et al. [55] indicated that ginsenoside Rg3 attenuated ADM-induced cardiotoxicity by improving oxidative stress-induced endothelial dysfunction. The mechanism involved reducing oxidative stress by activating AKT and up-regulating Nr2f2/ARE and then reducing the ROS level. However, the use of ginsenoside Rg3 was limited because of its low aqueous solubility and oral bioavailability. To improve the medical use of ginsenoside Rg3, Li et al. encapsulated ginsenoside Rg3 through spontaneous self-assembly of Pluronic F127 and found that they could alleviate cardiotoxicity by improving the calcium treatment and mitochondrial and metabolic functions while reducing the ROS [56]. Moreover, PG and its ginsenosides demonstrated antioxidant effects by augmenting the levels of antioxidant biomolecules and reducing lipid peroxidation products. You et al. found that PG attenuated ADM-induced heart failure by increasing myocardial glutathione peroxidase, macromolecular biosynthesis, and superoxide dismutase activity as well as reducing lipid peroxidation [57]. Similarly, 20(S)-ginsenoside Rh2 increased antioxidant biomolecule levels and reduced the content of MDA in ADM-treated mouse heart tissue [54].

3.5.3. Anti-apoptotic and autophagy regulation of PG and ginsenosides on chemotherapy-induced cardiotoxicity

The cardioprotective mechanisms of PG and its ginsenosides are closely related to their anti-apoptotic and autophagy regulation properties. First, ginsenosides attenuate ADM-induced cardiotoxicity by inhibiting apoptosis. Reportedly, ADM treatment of cardiomyocytes can result in the activation of caspase3, PARP, and P53 and the release of cytochrome c from the mitochondria [58,59]. Ginsenoside Rg1 inhibited ADM-induced cardiomyocyte apoptosis by increasing the phosphorylation of Akt and Erk pathways and the ratio of Bcl-2 to Bax while reducing the release of mitochondrial cytochrome c [60]. Additionally, Zhang et al. reported that ginsenoside Rb1 also alleviated ADM-induced cardiomyocyte apoptosis by reducing the expressions of caspase-3, caspase-8, and PARP in ADM-treated H9C2 cells [61]. Further study found that ginsenoside Rb1 inhibited ADM-induced cell apoptosis, at least in part by competing with ADM for the aryl hydrocarbon receptor to reduce the induction of CYP1A1, as evidenced by decreases in CYP1A1 and CYP1A2. Similarly, the cardioprotective effect of ginsenosides is achieved by regulating autophagy. Ginsenoside Rb1 could attenuate the ADM-induced decrease of cardiomyocyte viability and inhibit the increase of the autophagy-related structure, the conversion of light chain 3-I to light chain 3-II, and the decrease of p62 protein expression [62]. Additionally, endoplasmic reticulum stress is another cause of ADM-induced cardiac dysfunction and is closely associated with autophagy activation [63]. Xu et al. reported that the inhibition of endoplasmic reticulum stress and autophagy might be the mechanism by which ginsenoside Rg1 improved ADM-induced cardiac dysfunction. The results illustrated that this agent decreased ADM-induced autophagy-related 5; cleaved activating transcription factor 6, inositol-requiring enzyme 1, transcriptional intermediary factor 1, phosphorylated ribosomal protein S6 kinase beta-1, JNK 1, and Beclin1; and increased glucose-regulated protein 78 expression [64].

3.6. Effects of PG on chemotherapy-induced immunotoxicity

3.6.1. Chemotherapy-induced immunotoxicity

Chemotherapy drugs usually cause serious immunotoxicity, which seriously weakens the effect of the treatment and reduces the patient’s quality of life. Of these chemotherapy drugs, CY, which is an inducer of immunosuppression, can cause the production of serum cytokines, such as interferon-γ, TNF-α, IL-2, IL-10, and IL-12 [65]. Moreover, CY-induced oxidative stress and free radical damage induced immunosuppression. Recently, PG and its ginsenosides were confirmed to be immunomodulators after chemotherapy in numerous studies (Table 4).
The treatments of PG and its ginsenosides can improve chemotherapy-induced immunotoxicity by regulating the function of immune-related organs and cells and the levels or balance of immune-related cytokines and molecules. Chen et al. reported that the reverse effect of ginsenoside Rg3 on CY-induced immunosuppressive mice is related to the enhancement of immune organs and cells and the levels or balance of chemotherapeutic-induced immunotoxicity.

#### 3.6.2. Immunomodulation of PG and ginsenosides on chemotherapy-induced immunotoxicity

The treatments of PG and its ginsenosides can improve chemotherapy-induced immunotoxicity by regulating the function of immune-related organs and cells and the levels or balance of immune-related cytokines and molecules. Chen et al. reported that the reverse effect of ginsenoside Rg3 on CY-induced immunosuppressive mice was related to the enhancement of immune organs and cells and the levels or balance of chemotherapeutic-induced immunotoxicity.

Moreover, Lin et al. found that a significant difference was observed in the percentage of apoptotic cells, the ratio of Bcl-2 and Bax, the percentage of caspase-3, caspase-8, PARP, CYP1A1 and CYP1A2.

In conclusion, red ginseng extract and fermented RGE showed similar immunomodulatory activity to that of RGE, but the effect was not as strong as that of RGE. This action may be related to the processing time of RGE. Apart from processing time, different treatment methods will also affect the immunomodulatory effect of RGE. Kim et al. [70] observed an immunomodulatory effect of probiotic-fermented ERG (FRG), water-extracted RG (WRG), enzyme-treated eRG (ERG), and 50% ethanol-extracted RG (eRG) on CY-induced immunosuppressive mice. WRG, eRG, ERG, and FRG increased the levels of blood IFN-γ and white blood cells in CY-induced immunosuppressive mice and promoted the differentiation of Treg cells (except for WRG) and Th1 cells (especially FRG and WRG). Among them, FRG showed the strongest activity, which may have been caused by RG fermentation by probiotics, which promoted a better absorption of ginsenoside Rd and CK in the blood than that of unfermented RG. Ginsenoside Rg3, which is the most active natural biological component extracted from red ginseng, may be responsible for the immunomodulatory effect of red ginseng. The mechanism of the reversal effect of ginsenoside Rg3 on CY-induced immunosuppressive mice is related to the enhancement of immune organs, phagocytes, and T lymphocytes [71]. Notably, the chemotherapy-induced imbalance of Th1/Th2 cells, which caused an imbalance of immune-related cytokines and eventually led to an abnormal immune system, was reversed by ginsenoside Rg3. This effect was caused by increased expression of T-bet and interferon-γ and decreased expression of the GATA-binding protein 3 and IL-4 in...
the thymus and the spleen. Similarly, (20S)-ginsenoside Rh2 and its main metabolites including (24R)-pseudo-ginsenoside HQ and (24S)-pseudo-ginsenoside HQ balanced spleen T lymphocyte subsets and serum cytokines levels in CY-treated immunosuppressive mice [67].

3.6.3. Immunomodulation mechanisms of PG and ginsenosides on chemotherapy-induced immunosuppression

The mechanisms of PG and its ginsenosides in alleviating immunotoxicity are related to anti-inflammatory, anti-inflammatory, and fatty acids-regulatory activities. Chen et al. reported that the protein expressions of Nrf2, HO-1, NQO1, and other antioxidant enzymes were increased by PGRT and PGFR treatments in the spleen, which indicated that Nrf2/HO-1 and Nrf2/NQO1 signaling played an essential role in alleviating immunosuppression in CY-treated mice [66]. Meanwhile, the anti-inflammatory effect is an important way for white ginseng extract to restore CY-induced immunosuppression, and the underlying mechanism is related to the activation of the mitogen-activated protein kinase kinase 4 (MKK4)/JNK pathway [72]. The experimental results revealed that WRG not only increased the NO level by up-regulating inducible nitric oxide synthase expression and the expression of cytokines in INF-γ-induced macrophages but also enhanced natural killer cell activity and the proliferation of B- and T lymphocytes in the CY-induced immunosuppressive mouse model. Furthermore, the phosphorylation of MKK4 and JNK in the spleen was observed in INF-γ-induced macrophages. Additionally, because studies have found that metabolic dysregulation is one of the triggers leading to immune disorders [73], Qian et al. investigated the relationship between the immunoregulative effect and the metabolism-enhancing benefits of ginsenoside Rh2 [74] and found that ginsenoside Rh2 regulated fatty acid metabolism; regulation of fatty acid metabolism

3.7. Effects of PG on chemotherapy-induced hepatotoxicity

The central role of the liver in drug metabolism makes it vulnerable to toxic injury. Chemotherapeutic drugs, such as CP and CY, can cause hepatotoxicity, and the mechanisms involved include oxidative stress, apoptosis, and inflammation. Notably, PG and its ginsenosides with enhanced antioxidant, anti-apoptotic, and anti-inflammatory properties.
inflammatory activities were proven to attenuate chemotherapeu-
tic hepatotoxicity (Table 5).

Based on experimental evidence, PG and its ginsenosides exhibit
a promising hepatoprotective feature. Alrashed et al. discovered
that CP-induced hepatotoxicity was alleviated by PG. In CP-induced
liver-damaged rats, PG decreased the levels of serum alanine
aminotransferase and aspartate aminotransferase while alleviating
hepatic damage [75]. Another study discovered that the hep-
atoprotective potential of PG was correlated with its antioxidant,
anti-apoptotic, and anti-inflammatory effects in CY-treated rats
[76]. PG decreased pro-inflammatory genes, caspase-3, and MDA
levels while enhancing the expressions of Bcl-2 and antioxidant
enzymes. Notably, other researchers have conducted studies on the
antioxidant mechanism of PG and its ginsenosides and found that
the Nrf2 pathway provided a vital role in their anti-oxidative effect.
Zhu et al. [77] revealed that PG protected against CY-induced
hepatotoxicity by increasing Nrf2 expression and regulating the
dynamic balance of glutathione and bile acid. In addition, Gao and
his coworkers [78] reported that ginsenoside Rg1 effectively pro-
tected against CP-induced hepatotoxicity mainly by inhibiting
the binding of Keap1 and Nrf2, partly through p62 accumulation. More
importantly, ginsenoside Rg1 could prevent CP-induced hepato-
toxicity by increasing the production of Nrf2-related antioxidant
proteins in mice.

3.8. Effects of PG and ginsenosides on other chemotherapy-induced
side effects

3.8.1. Effects of PG and ginsenosides on ototoxicity caused by
chemotherapy

Chemotherapy-induced ototoxicity is characterized by irre-
sversible sensorineural hearing loss. Korean PG showed protective
effects against CP-induced ototoxicity by exhibiting anti-apoptotic,
antioxidant, and anti-inflammatory effects. In the ototoxicity model
of CP-induced auditory cell line House Ear Institute-Organ of Corti
1 (HEI-OC1), Korean PG reduced the CP-induced increase of ROS
and suppressed the CP-stimulated expressions of caspase-3 and poly-
ADP-ribose polymerase, which reflected the antioxidant and anti-
apoptotic effects of Korean PG [79]. Kim et al. further studied the
mechanism of Korean PG on the toxicity of CP to HEI-OC1 auditory
cells in vitro and found that Korean PG did not have antioxidant,
anti-apoptotic effects, and anti-inflammatory effects [80]. In an
in vivo study, CP-induced hearing threshold changes in mice and
damage to the hair cell array in primary Corti explants in rats could
be prevented by Korean PG. In an in vitro study, Korean PG sup-
pressed ROS production, the activation of the pro-apoptotic factor,
and pro-inflammatory factors in HEI-OC1 auditory cell lines.
Interestingly, one study reported that Korean PG at a low dose has
the most obvious antagonistic effect on CP-induced ototoxicity in
rats, especially in spiral ganglion neurons and brainstem neurons
[81]. In an in vitro study on the CP-treated HEI-OC1 cell line, Korean
PG alleviated CP-induced ototoxicity by decreasing apoptotic gene
expression while increasing anti-apoptotic gene expression. In the
rat model of CP-induced ototoxicity, low dose Korean PG could
significantly antagonize CP-induced ototoxicity in rats, especially in
spiral ganglion neurons and brainstem neurons, which reveals its
potential protection activity against ototoxicity after chemotherapy
treatment.

3.8.2. Effects of PG on adverse reactions in testicular toxicity caused
by chemotherapy

Testicular toxicity is one of the reasons that clinical chemo-
therapy is restricted and may lead to azoospermia and oligo-
spermia, thus affecting fertility. ADM is a common
chemotherapeutic drug with various side effects, including testic-
ular toxicity. Kang et al. reported that ginseng intestinal metabolite-
I had a protective effect against ADM-induced testicular toxicity
induced by [82]. Doxorubicin-induced reduction in body weight,
spermatogenic activity (Sertoli cells, re-proliferation, and the
epididymal index), serum lactate dehydrogenase, and creatine
phosphokinase levels can be restored by GIM. Additionally, GIM
attenuated germ cell injury and decreased the mRNA of phospho-
lipid hydroperoxide glutathione peroxidase.

3.8.3. Effects of PG on fatigue, hair loss, and cachexia caused by
chemotherapy

A variety of “disease behaviors” of CP in rats, including weight
loss, hypothermia, fatigue, and hyperalgesia, mimic several aspects
of cachexia as experienced by patients receiving chemotherapy. The
PG extract had a protective effect on cachexia model rats, showing
that it prevented CP-induced weight loss, hypothermia, hyper-
algesia, and reduced running time [83]. Additionally, a study on
cancer-related fatigue was conducted, and it was found that
BST204, a PG-purified dry extract, might improve cancer-related
fatigue by regulating inflammation and hematopoiesis [84]. In the
behavioral data, running wheel activity, and forced swimming time
increased because of the BST204 treatment. Additionally, BST204 not only increased the level of muscle glycogen activity and blood routine index but also decreased the serum levels of pro-inflammatory cytokines.

Chemotherapy-induced hair loss (CIA) is one of the most disturbing adverse reactions because it causes negative psychological perceptions in patients. The characteristic signs of CIA include decreased proliferation and increased apoptosis of hair matrix keratinocytes, suppression of hair growth, and premature catagen development. Korean PG suppressed these characteristic signs of CIA in the 4-hydroperoxycyclophosphamide-induced alopecia model. Additionally, Korean PG restored apoptosis-related protein expression induced by 4-hydroperoxycyclophosphamide in hair follicle cells, which means that the inhibitory effect of Korean PG on CIA might be related to the anti-apoptotic property [85].

4. Discussion

As a traditional Chinese medicine, PG has been used for thousands of years. Ginsenosides may be the efficacy basis of PG. In this paper, the therapeutic effects of PG and ginsenosides on adverse reactions of chemotherapy are reviewed (Fig. 1). The underlying mechanism may be related to an increase of antioxidant enzymes and anti-apoptotic, anti-inflammatory signals and immunostimulatory factors and a decrease in the pro-apoptotic, pro-inflammatory, immunosuppressive, and pro-oxidative indexes. Further study found that the mechanism involved multiple signal pathways, such as Nrf2/Keap1, P62/Keap1, JNK/P53/caspase3, MEK/ERK, AMPK/mTOR, Nrf2/HO-1, and PI3K/Akt (Fig. 2). Notably, among the ginsenosides reviewed in this paper, ginsenoside Rg3, as a rare product produced during processing, exhibits promising therapeutic efficiency against various adverse chemotherapy reactions, including nephrotoxicity, cardiotoxicity, immunity, and hematopoietic inhibition, which is in line with the clinical results [14,15]. Ginsenoside Rg3, as an approved drug, is applicable in the treatment of chemotherapy-induced side effects.

Additionally, although PG and ginsenosides can alleviate the side effects caused by chemotherapy, some shortcomings still cannot be ignored. The exact mechanism of PG and its ginsenosides is unclear, which may be attributed to the underlying mechanism involving multiple pathways and targets. Therefore, additional research methods, such as omics technologies (e.g., genomics, metabolomics, proteomics, transcriptomics), should be applied. By using these methods, researchers can study tissue and cellular structures, genes, proteins, and their interactions with molecules and then elucidate the exact mechanism of PG and its ginsenosides. In addition, attention should be paid to molecular docking technology. A recent study [86] simulated the docking of ginsenosides and anti-apoptotic proteins and found that ginsenosides, especially Rg1, Rg3, Rh2, and Rf, could be effective compounds for reducing the overexpression of anti-apoptotic proteins (such as BCL-2, BCL-XL, and MCL-1). However, this novel method has not been applied to help us understand effect of PG and its ginsenosides on chemotherapy-caused side effects. Moreover, the intestinal flora has become a hotspot in research on drug mechanisms. Several studies have shown that natural products can treat diseases by affecting the intestinal flora [87,88]. However, so far, whether PG and its ginsenosides regulate the side effects of chemotherapy through intestinal flora is unclear. Notably, the oral bioavailability of ginsenosides is low because of their high molecular weight, low water solubility, and poor gastrointestinal stability. Thus, the bioavailability of ginsenosides should be improved by establishing effective drug delivery systems and various drug delivery routes, including micelles and emulsion drug delivery systems. Moreover, studies have reported that the inhibitory actions of PG and its ginsenosides on the side effects of chemotherapy were mostly limited to animals and cells. To elucidate the role and mechanism of PG and its ginsenosides in inhibiting the side effects induced by chemotherapy in humans, longitudinal human studies are warranted to evaluate their effectiveness, safety, and tolerance.

**Fig. 1.** Effects of PG and its ginsenosides on the side effects caused by chemotherapy. PG and its ginsenosides were used to treat chemotherapy-induced side effects, including nephrotoxicity, gastrointestinal mucosa injury, cognitive impairment, myelosuppression, cardiotoxicity, immunotoxicity, hepatotoxicity, and ototoxicity, mainly through the regulation of factors and signaling pathways related to oxidation, apoptosis, inflammation, autophagy, and immunity.
5. Conclusion

This review briefly summarizes the therapeutic potential of PG and its ginsenosides in reducing the side effects of chemotherapy in vivo and in vitro and explains the mechanisms by which PG and its ginsenosides alleviate chemotherapy-induced side effects. The underlying molecular mechanism can be partially elucidated by the roles of the Nrf2/HO-1, P62/keap1/Nrf2, JNK/P53/caspase3, MEK/ERK, AMPK/mTOR, MKK4/JNK, and PI3K/Akt signaling pathways. Nrf2/HO-1 and P62/keap1/Nrf2 signaling pathways are classic antioxidant pathways. PG or its ginsenosides exert antioxidant effects by up-regulating P62, Nrf2, and HO-1 expressions and down-regulating keap1 expression. JNK/P53/caspase3 and MEK/ERK signaling pathways are related to cell apoptosis. PG or its ginsenosides show anti-apoptosis effects by inhibiting the activation of JNK, P53, and caspase3 and activating the expressions of MEK and ERK. AMPK/mTOR signaling pathway plays a crucial role in the genesis and progression of autophagy. PG or its ginsenosides regulate AMPK/mTOR pathways by increasing mTOR expressions and suppressing AMPK expressions. MKK4/JNK is an essential pathway by which PG and its ginsenosides alleviate chemotherapy-induced immunosuppression. PG and its ginsenosides regulate MKK4/JNK pathways by promoting MKK4 and JNK expressions. The regulation of fatty acid synthase (FASN) is associated with immunomodulatory effects. PG or its ginsenosides regulate FASN by inhibiting the activation of PI3K, AKT, and SREBP-1.

5. Conclusion

This review briefly summarizes the therapeutic potential of PG and its ginsenosides in reducing the side effects of chemotherapy in vivo and in vitro and explains the mechanisms by which PG and its ginsenosides alleviate chemotherapy-induced side effects. The underlying molecular mechanism can be partially elucidated by the roles of the Nrf2/HO-1, P62/keap1/Nrf2, JNK/P53/caspase3, MEK/ERK, AMPK/mTOR, MKK4/JNK, and PI3K/Akt signaling pathways. In conclusion, because of their less desirable side effects and antioxidative, anti-inflammatory, and anti-apoptotic actions, PG and its ginsenosides are potential agents for the prevention and treatment of chemotherapy-induced side effects.
