\textbf{Objective:} To evaluate the available evidence regarding the clinical effectiveness of different types of anchorage devices. \textbf{Methods:} A comprehensive literature search of different electronic databases was conducted for systematic reviews investigating different anchorage methods published up to April 15, 2021. Any ongoing systematic reviews were searched using PROSPERO, and a grey literature search was undertaken using Google Scholar and OpenGrey. No language restriction was applied. Screening, quality assessment, and data extraction were performed independently by two authors. Information was categorized and narratively synthesized for the key findings from moderate- and high-quality reviews. \textbf{Results:} Fourteen systematic reviews were included (11 were of moderate/high quality). Skeletal anchorage with miniscrews was associated with less anchorage loss (and sometimes with anchorage gain). Similarly, skeletal anchorage was more effective in retracting anterior teeth and intruding incisors and molars, resulting in minor vertical skeletal changes and improvements in the soft tissue profile. However, insufficient evidence was obtained for the preference of any anchorage method in terms of the duration of treatment, number of appointments, quality of treatment, patient perception, or adverse effects. The effectiveness of skeletal anchorage can be enhanced when: directly loaded, used in the mandible rather than the maxilla, used buccally rather than palatally, using dual rather than single miniscrews, used for en-masse retraction, and in adults. \textbf{Conclusions:} The level of evidence regarding anchorage effectiveness is moderate. Nevertheless, compared to conventional anchorage, skeletal anchorage can be used with more anchorage preservation. Further high-quality randomized clinical trials are required to confirm these findings.

\textbf{Key words:} Orthodontic anchorage procedures, Anchorage loss, Orthodontic mini-implant

INTRODUCTION

Orthodontic treatment of malocclusion such as a full Class II relationship, dentoalveolar protrusion, or severe crowding often requires premolar extraction. The treatment outcomes in these cases depend on the closure of the extraction spaces while adequately controlling the anchorage teeth. Orthodontic anchorage is defined as the resistance to unwanted tooth movement. Anchorage control is of great importance in extraction and during the space closure stage. Conventionally, different methods and devices have been used for anchorage control, e.g., bonding of second molars, the use of a transpalatal arch (TPA) with or without a Nance button, lingual arches, headgear, or intermaxillary elastics. Each method can be used according to the clinical situation and has its advantages and disadvantages. For instance, extraoral appliances require greater patient compliance and may be associated with facial trauma. In contrast, intraoral appliances (such as TPAs) have not been shown to be effective despite being widely used. Recently, orthodontic temporary anchorage devices (TADs) were introduced as skeletal anchorage devices that can provide maximum to absolute anchorage and are compliance-free. TADs can take the form of implants, plates, screws, or screw-retained devices, which are inserted into the bone to provide resistance to unwanted tooth movement (indirect anchorage) or serve as a point from which orthodontic traction can be applied (direct anchorage).

Studies have suggested that anchorage could be better preserved when using two-step retraction by initially retracting the canine followed by retraction of the incisors than when using en-masse retraction of the six anterior teeth. However, this is still a controversial subject clinically, especially when considering the variety of anchorage designs.

Although TPAs have been found to have very limited effectiveness in terms of anchorage control, especially the mesial movement of the anchored molars, by using finite element analysis, some clinical trials have suggested using them as secondary anchorage devices when maximum anchorage is not required.

Several systematic reviews have compared the clinical effectiveness of different types of anchorage devices in terms of the amount of anchorage loss; sagittal and vertical dental, skeletal, and soft tissue changes; duration of treatment; quality of treatment; patient perception; and adverse effects. However, to date, researchers have not provided a robust and clear answer to the following question: which anchorage method is the best during retraction of anterior teeth according to these different treatment outcomes?

This overview was designed to evaluate the available evidence (on a systematic review level) regarding the clinical effectiveness of different types of anchorage devices during the retraction of anterior teeth. The reason for conducting an overview of systematic reviews was that all the available systematic reviews varied in terms of the types of anchorage devices, method and time of assessment, types of tooth movement, and treatment outcomes. Therefore, this overview aimed to gather all the available evidence for each intervention, evaluate the level of evidence, and then categorize the outcomes to translate the evidence into practice. This overview should be able to identify what is known in this topic area, what remains unknown, and where investigators should focus their efforts in future research projects.

MATERIALS AND METHODS

Ethical approval was not required for this study as there was no individual participation, intervention, or personal data collection. This overview was prepared in line with the Preferred Reporting Items for Systematic Review and Meta-Analyses (PRISMA) statement, according to the methodological guidelines for conducting overviews of systematic reviews of health care intervention, as provided by Smith et al.

Protocol and registration

The protocol for the present review was registered with PROSPERO (registration number: CRD42020218197).

Eligibility criteria

The eligibility criteria were determined according to the Population, Intervention, Comparison, Outcome, and Study design (PICOS) scheme:

Population: patients of any age undergoing orthodontic treatment with fixed appliances and requiring retraction of anterior teeth with anchorage control after premolar extraction.

Intervention: orthodontic treatment with fixed appliances and any type of anchorage reinforcement device.

Comparison: orthodontic treatment with fixed appliances and any other type of anchorage reinforcement device.

Outcome: comparison of the effectiveness of anchorage devices.

Study design: systematic reviews with or without meta-analyses. In case of Cochrane reviews, the most recent publication was included, and all previous versions were excluded. Studies with any other design or without orthodontic treatment were also excluded, as were systematic reviews of in vitro or animal studies.

Score of each review represents the number of “YES” answers in the A Measurement Tool to Assess Systematic Reviews (AMSTAR 2) checklist. However, this may not always reflect the quality as items do not have the same weight.

RCT, randomized controlled trial; CCT, controlled clinical trial; TPA, transpalatal arch; SN-MP, sella-nasion to mandibular plane angle.
Information sources, search strategy, and study selection

A comprehensive literature search was conducted for systematic reviews published up to April 15, 2021 by using the following key terms: “anchorage”, “conventional”, “transpalatal”, “screw”, “implant”, “retraction”, “systematic review”, and “meta-analysis”. The search was accomplished using the following electronic databases: MEDLINE via OVID (1946 to April 15, 2021), EMBASE (1974 to April 15, 2021), AMED (Allied and Complementary Medicine Database, 1985 to April 15, 2021), PubMed (inception to April 15, 2021), and Web of Science (1900 to 2021). Any ongoing systematic reviews were searched using PROSPERO, and a grey literature search was undertaken using Google Scholar and OpenGrey (www.opengrey.eu/). No restrictions were applied in terms of language, date, and status of publication, or the age of treated patients. All relevant articles were identified, retrieved, and assessed for eligibility of inclusion by two authors (Y.A.Y. and S.A.N.). Any disagreement was resolved by discussion to reach consensus or, alternatively, by consulting a third author (D.R.B.).

Data items and collection

After screening the eligible systematic reviews, the following data were extracted independently and in duplicate by two authors (Y.A.Y. and S.A.N.): (1) authors; (2) year of publication; (3) study design; (4) number of studies included; (5) type of studies; (6) number of participants; (7) period of search; (8) name of journal; and (9) objectives of the study (Table 1).

Quality assessment in individual studies

Two authors (Y.A.Y. and S.A.N.) assessed the included reviews independently by using the AMSTAR 2 quality assessment tool (A Measurement Tool to Assess Systematic Reviews)\(^5\) (Table 2). Any disagreement was initially resolved by discussion or in conjunction with a third author (D.R.B.), if necessary. The level of evidence according to the AMSTAR 2 is presented in Table 3.

PICO, Population, Intervention, Comparison, and Outcome.
Summary measures and approach to synthesis

Data pooling was planned to qualitatively assess the effectiveness of the critically appraised topic as systematic reviews per se do not have primary data.

RESULTS

Study selection and characteristics

A total of 332 potentially eligible studies were identified. After excluding duplicates, 274 studies were left. Thereafter, initial screening of the titles and abstracts reduced the number of studies to 34. After full-text assessment, 20 reviews were excluded (4 reviews were not systematically designed or were older versions of Cochrane reviews and 16 were not relevant to the aim of this overview), and the remaining 14 systematic reviews were included (Figure 1).

A summary of the characteristics of the included systematic reviews is presented in Table 1. The included studies were published between 2006 and 2021. Meta-analyses were carried out in 85.7% of the systematic reviews (12/14 systematic reviews).

Data synthesis

Owing to the lack of primary data, differences in types of anchorage devices used, method, and time of anchorage loss measurement, further meta-analysis was not possible. The data were, therefore, synthesized qualitatively by using thematic synthesis by identifying the most prominent and important themes with the findings summarized accordingly.

Quality of evidence

According to the AMSTAR 2 checklist, the quality of the included reviews was variable: 2 (14.3%) had critically low quality, 1 (7.1%) had low quality, 9 (64.3%) had moderate quality, and 2 (14.3%) had high quality (Table 1). Most of the AMSTAR 2 items were covered to a varying degree. Only one review\(^\text{22}\) reported the source of funding of the included studies (Table 2). Complete

AMSTAR 2, A Measurement Tool to Assess Systematic Reviews.

*Multiple non-critical weaknesses may diminish the confidence in the review, and it may be appropriate to move the overall appraisal down from moderate to low confidence.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Review and Meta-Analyses) flow diagram of the literature selection process. RCT, randomized controlled trial.
amount of anchorage loss between the two methods-
skeletal anchorage than with conventional anchorage.
consensus in terms of greater anchorage preservation with
Anchorage loss was measured using different methods, e.g.,
classification analyses, or using reference points clinically. The time of measurement was also variable, i.e.,
from the start of treatment until achieving a Class I canine relationship or to the end of space closure,
during space closure, and at the start and end of active orthodontic treatment.
Amount of anchorage loss
The mean anchorage loss, as represented by the mesial
movement of the maxillary first molar, was significantly
greater with conventional anchorage devices (TPAs,
headgear, Nance appliances, banding of second molars,
and differential anchorage methods) than with mini-
screws.
The results of the included systematic reviews in terms of
the amount of anchorage loss and the influence of
anchorage method on vertical change of the maxillary
first molar, anterior teeth retraction, vertical change of
maxillary incisors, skeletal changes, soft tissue changes,
duration of space closure, overall duration of treatment,
number of appointments, quality of treatment, patient
perception, and adverse effects are described in detail in
Table 4.

DISCUSSION
Since the effectiveness of anchorage devices had been investigated by various heterogenous systematic
reviews, the logical next step was to perform an overview
of these reviews. This would allow the findings of
these separate reviews to be appraised, compared, and
contrasted in order to highlight and summarize the
best available evidence from more than one systematic
review in a single document. This consequently aids in
evidence-based clinical decision-making.
Amount of anchorage loss
All the included systematic reviews showed a con-
sensus in terms of greater anchorage preservation with
skeletal anchorage than with conventional anchorage.
The amount of anchorage loss between the two meth-
ods was roughly 2 mm, and this can be considered of
clinical importance since it represents about 25% of the
extraction space. This consistent finding can be attrib-
uted to the fact that miniscrews are solely anchored by
bone, and so they usually provide maximum anchorage
with zero effect on the first molars. Alternatively, they
either fail or migrate; however, the included systematic
reviews provided no evidence regarding the side effects
of migration. Becker et al. and Khlef et al. reported
that skeletal anchorage not only preserved the anchorage
but also induced distalization of the molars. This
might be explained by the friction between the archwire
and molar tube during the sliding of the wire during
incisor retraction. This friction is the result of the direc-
tion of retraction (distal and intrusive) that could cause
binding of the archwire in the molar tube, and hence,
the force will be transmitted through the archwire to the
dentin. The greater distal tipping of the molars with
miniscrews, albeit non-statistically significant, could be
the result of the lack of a reactive force on the molars
during the retraction of the anterior teeth. Additionally,
this distal tipping could be attributed to the friction
between the archwire and molar tube when the distal
force is transmitted through the archwire and results in
distal tipping of the molars.
The finding of less anchorage loss with dual mini-
screws than with a single miniscrew is logical and
related to the greater stability and correspondingly
lower failure with dual miniscrews. On the other hand,
the reduced anchorage loss in the mandible than in the
maxilla whether between miniscrews and conventional
anchorage or between miniscrews themselves may be
due to the higher density and less resilience of the man-
dibular bone, which provide more stability for skeletal
anchorage, as miniscrews rely on mechanical retention
and not osseointegration. The finding that anchorage
loss was greater for younger patients could also be
attributed to the quality of bone, which was denser with
higher cortical thickness at specific sites in the maxilla
and mandible of older patients than of younger pa-
tients, and hence provided greater stability for mesial
molar movement. Nevertheless, further investigations
are needed to confirm this finding.
Anchorage loss was greater when the miniscrew/im-
plant was placed palatally rather than buccally. This
can be correlated with another finding where greater
preservation was observed with direct anchorage than
with indirect anchorage. In general, with indirect
anchorage, the force of retraction is applied to the
tooth that is ligated by the miniscrew. Therefore, any
resilience/deformation of the connecting wire, or loose
ligation, can lead to anchorage loss. The fact that mini-
screws that are placed palatally are mostly used for indi-
rect anchorage can explain these findings.
The results of the included systematic reviews in terms of anchorage methods and their influence on different factors are presented in Table 4.

**Table 4. The results of the included systematic reviews in terms of anchorage methods and their influence on different factors**

</table>

According to the results of Papadopoulos et al.,21 one should be aware that any pretreatment mesial drifting of the molars can be a risk factor for anchorage loss. Hence, the implementation of skeletal anchorage may be necessary during treatment. A TPA alone does not prevent molar mesial movement and is comparable to “no anchorage”. Using headgear can enhance anchorage when compared to that ob-
Table 4. Continued

Anchorage method and anterior teeth retraction

- There was statistically significantly greater incisor retraction in favour of miniscrews when compared to conventional anchorage methods. The difference was 1.37 mm (95% CI: 0.83 to 1.91 mm), 23 1.5 mm (95% CI: 1.17 to 1.84 mm), 26 0.46 mm (95% CI: 0.04 to 0.87 mm) with better incisor inclinations (mean difference 0.74˚, 95% CI: 0.25˚ to 1.23˚), 28 and 0.47 mm (95% CI: 0.07 to 0.87 mm) (however, this significance was only for patients older than 18 years). 31
- Incisor tipping was slightly greater but the difference was not statistically significant with miniscrews, 23 while the reverse was found with another review 26 but again with no significant difference.
- When both anchorage methods were used with en-masse retraction, no significant differences in incisor retraction and incisor inclination were reported. 29
- There was significantly greater canine retraction in the two-step retraction technique with the use of miniscrews than with conventional anchorage methods both in the maxilla (mean difference 0.43 mm, 95% CI: 0.16 to 0.69) and the mandible (mean difference 0.26 mm, 95% CI: 0.02 to 0.49). Distal tipping of the canines was also greater in the miniscrew group than in the conventional anchorage group in both arches by about 3˚, however this difference was not statistically significant. 32

Anchorage method and vertical change of the maxillary incisors

- Incisors were intruded with miniscrews and extruded with conventional anchorage methods with a significant mean difference of 2.48 mm (95% CI: 1.77 to 3.19 mm) 28 and 1.87 mm (95% CI: 0.09 to 3.65 mm). 29 Similar results were found with another review but with no significant difference. 31

Anchorage method and skeletal changes

- Miniscrews as compared to conventional anchorage methods did not show a significant difference in SNA angle, but there was a significant reduction in SN-MP angle with miniscrews by 1.12˚ (95% CI: 0.03˚ to 2.21˚). 26
- En-masse retraction with miniscrews and two-step retraction with conventional anchorage: no significant differences in terms of SNA, SNB, ANB, and SN-MP angles. 28
- En-masse retraction with miniscrews and conventional anchorage methods: no significant differences of SNA, SNB, and ANB, while, SN-MP was significantly increased with conventional anchorage (mean difference 1.12˚). 26

Anchorage method and soft tissue changes

- The nasolabial angle increased with miniscrews significantly by 3.52˚ (95% CI: 1.17˚ to 5.87˚) 28 and 4.73˚ (95% CI: 1.30˚ to 8.17˚). 28
- Two reviews found a significant reduction of upper lip with miniscrews. 26,29 The reduction of upper lip to E-line (0.73 mm, 95% CI: 0.28 to 1.17 mm) with miniscrews rather than conventional anchorage methods. 28 Another review 26 found that there was a greater but not statistically significant reduction of upper lip to E-line in the miniscrew group.
- There was a significantly greater lower lip to E-line reduction with miniscrews compared to conventional anchorage methods (0.95 mm, 95% CI: 0.21 to 1.69 mm). 28 While, no significant difference in lower lip was reported in a different review. 24
- There was a tendency to a decrease in the facial convexity angle with skeletal anchorage methods than with conventional anchorage methods. 26,28,29

Anchorage method and duration of space closure

- The duration of space closure was not significantly shorter with surgical anchorage than with conventional anchorage methods (the difference was only 12 days). 22
- No significant difference in the duration of space closure between miniscrews and TPA groups. 30
- Although the duration of space closure was not significantly different between single and dual miniscrews, the difference was 2.19 months (95% CI: −1.97 to 6.35 months) in favour of single miniscrews. 22

Anchorage method and overall duration of treatment

- A non-significant reduction in the overall duration of treatment was found with surgical anchorage (miniscrews and mid-palatal implants) by 0.15 years (95% CI: -0.07 to 0.37 years) than that with conventional anchorage methods. 22 Using miniscrews also did not show a significant difference in the duration of treatment in comparison to TPA, Nance appliances, or headgear. Overall duration of treatment was shorter by 1.1 months (95% CI: -1.79 to 3.98 months) in favor of those treated using miniscrews for anchorage. 30
- A similar finding was identified of no significant shorter duration of treatment with miniscrews than conventional anchorage when both were used with en-masse retraction (mean difference 1.15 months). 28
- One meta-analysis found significant shorter treatment duration when using miniscrews by 4 months (95% CI: 2.21 to 5.79 months) than when using conventional anchorage. 23
tained using TPAs. This is due to the use of the extra-oral skeletal component of the headgear. However, the headgear is only used part-time, and generally, it is less acceptable than are miniscrews. Furthermore, both TPAs and headgears showed greater anchorage loss than did miniscrews.

When en-masse retraction with miniscrews was compared with two-step or en-masse retraction with conventional anchorage, the result was in line with the above findings and led to the conclusion that even with increasing numbers of retracted teeth, the skeletal anchorage did not have any adverse effect on the anchored teeth. Miniscrews were also more effective in preserving the anchorage than were conventional anchorage methods in the two-step retraction technique.

Anchorage method and vertical change of the maxillary first molar

The vertical force vector associated with retraction using miniscrews explains the finding of intrusion of the molars, as the incisors will be subject to distal and intrusive force vectors due to the position of the miniscrew, and hence, the intrusive force will be transferred to the molars via the archwire. Therefore, the intrusive force on the molars while retracting the incisors with miniscrews could be beneficial for patients with clockwise rotation of the mandible, anterior openbite, and Class II malocclusion. Even minor intrusion of the posterior teeth of approximately 1 mm has been reported to produce a significant upward and forward movement of the chin of approximately 3–4 mm.

Anchorage method and anterior teeth retraction

Although incisor retraction was greater with miniscrews and was statistically significant, this was of less clinical significance (0.46–1.5 mm) when compared to the amount of anchorage loss. The greater incisor retraction may be related to the greater stability of the bone than that of the tooth as an anchorage unit as well as to the greater space available for incisor retraction with miniscrews (due to less anchorage loss).

The same is true for canine retraction. Incisor inclination and tipping depend on factors such as the size of the archwire, point of force application, and presence or absence of third-order bends, which do not have a direct relationship with the anchorage method. Khlef et al. reported that when using temporary skeletal anchorage devices, the incisors would be retracted via controlled tipping and bodily movement, whereas with conventional anchorage, the incisors would

be retracted via controlled and uncontrolled tipping. Therefore, optimal incisor inclination can be achieved with skeletal anchorage devices.

**Anchorage method and vertical change of the maxillary incisors**

As with molar vertical changes, the incisors will be subject to an intrusive force when retracted with miniscrews.\(^{28,29,31}\) This is the effect of the line of force application that is higher with miniscrews than with conventional anchorage methods where the point of force application is on the molars, which may result in a downward vector and extrusion. The length of the power arm can also play a role in the amount of vertical change, as decreasing the height of the power arm results in increasing the intrusive force on the incisors.\(^{28}\)

**Anchorage method and skeletal changes**

Since the effect of incisor retraction, whether with miniscrews or with conventional anchorage methods, is mainly dental, its reflection on skeletal components is mainly limited to the skeletal regions that are affected indirectly by the dentition. Consequently, the difference in incisor retraction between the different anchorage methods will rarely influence sagittal jaw position, and hence, it is insufficient to be shown as a difference in the sella–nasion–point A (SNA), sella–nasion–point B (SNB), and point A–nasion–point B (ANB) angles. However, intruding the molars with miniscrews and extruding them with conventional anchorage can influence the vertical skeletal measurements as shown with the Sella-Nasion to Mandibular plane angle (SN-MP) angle.\(^{26,29}\) Nevertheless, this difference can be masked if the amount of vertical molar change is minimal between the two anchorage methods, as detailed in the systematic review by Khlef et al.\(^{28}\) where the molar vertical change was only 0.61 mm, and hence, no significant difference in the SN-MP angle was revealed. The meta-analyses by Xu and Xie\(^{26}\) and Khlef et al.\(^{29}\) found similar differences in the SN-MP angle between skeletal and conventional anchorage (1.12°), which in general was not of clinical significance.

**Anchorage method and soft tissue changes**

The greater amount of incisor retraction with miniscrews can explain the increase in the nasolabial angle, greater reduction of the upper lip to the E-line, and the tendency of decreasing the facial convexity.\(^{26,28,29}\) However, it is difficult to explain that when the mean differences in incisor retraction between the two anchorage methods were 1.5 mm\(^{26}\) and 0.46 mm,\(^{28}\) the mean differences in the nasolabial angle increased by 3.52° and 4.73°, respectively, unless a growth factor is considered to play a role in this process.

**Anchorage method and duration of space closure/treatment**

According to the decision algorithm by Jadad et al.,\(^{38}\) the evidence about the non-significantly shorter duration of treatment with miniscrews than with conventional anchorage\(^{22,28-30}\) outweighs that of the significantly shorter duration with miniscrews.\(^{23}\) This together with the non-significant difference between skeletal anchorage and conventional anchorage in the duration of extraction space closure\(^{22,30}\) could be explained by the same reason. If miniscrew failures occur, greater time will be required for bone healing before reinsertion and treatment resumption. Moreover, despite the more effective retraction with miniscrews as anchorage, the greater anchorage loss with conventional anchorage devices results in a smaller extraction space; hence, the time required to close that space with conventional anchorage will be shortened.\(^{30}\)

The difference in the duration of space closure between single and dual miniscrews (2.19 months in favor of a single miniscrew) was not statistically significant, and was derived from the findings of only one study, and hence, no meta-analysis was performed.\(^{22}\) Therefore, this finding may be due to chance.

**Anchorage method and number of appointments**

The number of appointments to complete treatment correlated with the technique used for space closure. Since skeletal anchorage is usually used with en-masse retraction and conventional anchorage with two-step retraction, this may indicate the need for less appointments with skeletal anchorage than with conventional methods. However, the number of appointments was reported with contradicting results in two reviews,\(^{22,30}\) each of which took its information from one study, and did not consider factors such as the miniscrew failure rate and surgical healing of the mid-palatal implant.

**Anchorage method and quality of treatment**

Not enough evidence was obtained to determine which anchorage methods were associated with better outcomes, because the available information was derived from only one meta-analysis,\(^{30}\) which in turn obtained data from one study.

**Anchorage method and patient perception**

Both miniscrews and conventional anchorage methods resulted in a comparable level of patient discomfort as each had disadvantages. Miniscrews are associated with pain during insertion and removal, while conventional methods are characterized by their bulkiness, which is unpleasant for patients. However, the general feedback with miniscrews is positive, especially if they are the pre-drilling type. Interestingly, some of the discomfort re-
ported by Jambi et al. was due to a surgical procedure that was not relevant to most of the skeletal anchorage.

**Anchorage method and adverse effects**

One meta-analysis found that the failure rate of the anchorage method with conventional anchorage methods was greater than that with miniscrews. However, miniscrew success depends on biological factors, while that of conventional methods is mainly dependent on the durability of the cementing material. Reusing conventional methods seems easier and quicker than using miniscrews, but evidence on this aspect is insufficient. Miniscrew failure rate was approximately 10–12%, and it did not differ between early and delayed loading.

**CONCLUSION**

1. The level of evidence regarding the effectiveness of anchorage methods is moderate. High-quality randomized clinical trials are hence warranted. According to the available evidence, skeletal anchorage with miniscrews is clinically more effective than are conventional anchorage methods, especially in preventing horizontal mesial molar movement.

2. During space closure, skeletal anchorage is more effective than conventional anchorage for the following:
   - Retraction of anterior teeth.
   - Intrusion of the incisors and molars.
   - Minor decrease in the vertical skeletal relationship.
   - Improving the soft tissue profile.

3. There was insufficient evidence to determine the benefit of specific anchorage methods for the following:
   - Duration of space closure and overall duration of treatment.
   - Number of appointments.
   - Quality of treatment.
   - Patient perception and adverse effects.

4. The effectiveness of skeletal anchorage can be enhanced as follows:
   - When directly loaded.
   - When placed in the mandible rather than in the maxilla.
   - When placed buccally rather than palatally.
   - When using dual miniscrews rather than a single miniscrew.
   - When used for en-masse retraction.
   - When used in adult patients.
